1.0 Security Concepts

1.1 Security Introduction

As you study this section, answer the following questions:

- What is information security?
- What challenges does a security professional face?
- What aspects create a proactive approach to security?
- What is the difference between integrity and non-repudiation?
- What are the three main goals of the CIA of Security?
- What are the key components of risk management?
- What are the three types of threat agents?

The key terms for this section include:

Term	Definition
Security operations center (SOC)	The location where security professionals monitor and protect critical information assets in an organization.
Development and operations (DevOps)	A combination of software development and systems operations and refers to the practice of integrating one discipline with the other.
DevSecOps	A combination of software development, security operations, and systems operations and refers to the practice of integrating each discipline with the others.
Computer incident response team (CIRT)/computer security incident response team (CSIRT)/computer emergency response team (CERT)	Team with responsibility for incident response. The CSIRT must have expertise across a number of business domains (IT, HR, legal, and marketing, for instance).

This section helps you prepare for the following certification exam objectives:

Exam	Objective

CompTIA Security+ SY0-701	1.1 Compare and contrast various types of security controls.
	• Categories
	  ○ Technical
	  ○ Managerial
	  ○ Operational

	○ Physical 1.2 Summarize fundamental security concepts. • Confidentiality, Integrity, and Availability (CIA) 2.1 Compare and contrast common threat actors and motivations. • Threat actors ○ Nation-state ○ Organized crime

1.1.1 The Security Landscape (Lesson Video)

Transcript:

Welcome to TestOut's Security Pro course. This course is designed to help you understand the Information security landscape and will prepare you to become a security professional.

But before we can dive into the ever-changing murky waters that is information security, we first need to talk about the security landscape that all security professionals must face.
In today's world, cyber criminals are a very real and dangerous threat. One way to think about Information security is that of a never-ending arms race, with the sophistication of the weapons being used advancing exponentially. Every day cyber criminals are finding new and innovative ways to exploit and infiltrate even the most secure systems and the security world is barely able to keep up.
Gone are the simple days of protecting a system from the random individual hacker. Instead, we are now combating a very organized, advanced, and powerful force that comes in many different forms, from script kiddies to nation states, organized crime to hacktivists, and everything in between.
Our job as a security professional is to defend against these organizations and the various techniques they use. Often times this means we need to think like they do look at our system and network from the eyes of an attacker. It also means we need to try to be one step ahead of them at all times. However, this is becoming more and more difficult as the number of internet-connected devices increases and the speed at which people expect new technologies to emerge. See, the faster new technology is developed and created, the less time it has to be thoroughly tested for vulnerabilities, holes, exploits, et cetera. In addition, each new device that connects to a network presents a new point of entry for an attacker that didn't exist before. Even more unsettling are the exploits that haven't even been discovered yet that attackers could using in the wild.
Because of all these variables, the goal for security professionals can never be that of eliminating attacks or breaches, that's impossible.
Now, I'm not saying this means we should just give up. We still need to secure our systems and take all the necessary precautions in order to reduce the threat surface. However, know that if your system is connected to the internet, then it's essentially impossible to protect your network from any and all attacks.
Understanding this, a security professional's goal should instead be to minimize the occurrence of attacks and reduce the damage caused by a breach. In other words, you need to properly secure and protect systems while at the same time understanding that a breach is going to occur. And when it does, you need to be able to identify the moment the breach occurred and stop it as fast as possible.
Doing this requires you take a proactive approach to security. But how do you do that?
Some obvious aspects of this approach include keeping systems up to date, implementing proper policies and procedures, hardening systems and networks, and so on. But another, often times neglected, aspect of this approach includes being informed.
Because the security landscape is ever-changing, you need to be extra diligent in keeping up to date on the most recent vulnerabilities and exploits used by hackers as well as the latest security techniques and technologies used by security

professionals. The internet is an endless supply of information, so be sure to use it. Blogs, news outlets, forums, podcasts, the list goes on, these are all great resources that will help you keep up to date on the latest security trends. Remember, as a security professional, it's your job to try to stay one step ahead of an attacker. You can do this by taking a proactive approach to security. Stay informed, read the landscape, know your systems and network, and understand that you can only protect a network to a point. Beyond that, it's your job to know what an attack looks like and stop it before any substantial damage can occur.

1.1.2 Security Concepts (Lesson Video)

Transcript:

In order to be an effective security professional, you need to be familiar with the concepts and the roles surrounding information security. This will help you understand the industry terms and lingo, and it will also provide a lot of context as you progress through this course.

The first information security concept that you need to be familiar with is that of an asset.
An asset is simply something that has value to an individual or an organization. This can be a physical device, such as a laptop or iPad, or it can be electronic information, such as a pdf document on a server. However, most of the time we're talking about an asset we mean the latter.
For example, let's suppose we have a server in our organization, and on this server there is a database that contains customer information, including credit card numbers and order history. This database has a lot of value to the organization and is therefore considered an asset.
The next security concept that you need to be aware of are threats. Threats represent anything that has the potential to cause the loss of an asset.
And notice I said has the potential to cause the loss of an asset. A threat isn't the actual loss of an asset. It's merely the potentialâ€""the riskâ€""that an asset could be stolen.
A threat can come in many different forms. It can be a virus, a Trojan, an external hacker, an internal employee. Because threats come in all shapes and sizes, sometimes we refer to them as blended threats.
To continue with our example, some threats to our customer database include ransomware, data exfiltrationâ€""which is a fancy way of saying stealing dataâ€""Trojans, and hackers.
Next, we have the threat agent. A threat agent is the actual person or entity that carries out a threat.
When it comes to threat agents, there are a few characteristics, or attributes, that can categorize them. For example, threat agents can be internal or external; they can have a little to no resources or funding, or they can be heavily funded with a lot of resources; they can also be opportunisticâ€""that is, they are simply attacking a system because it has a vulnerabilityâ€""or they can have a specific intent or motive.
Now, within these threat agent categories, there are different types of actorsâ€""the type of entity carrying out the attack. For example, an actor could be an organized crime syndicate trying to steal credit card information. An actor could also be a nation state trying to steal classified information. Even business competitors can be a type of actor who try to steal company secrets in order to gain an economic edge.
One example of a nation state actor you might be familiar with is North Korea. On November 24, 2014, North Korean hackers gained access to Sony Pictures networks and stole confidential information, including employee records, personal emails, and copies of unreleased movies. The information was then released to the public on the internet.
In order for threat agents to carry out a threat, they need an openingâ€""a weakness in the system. This is known as a vulnerability.
For example, a vulnerability could be a disgruntled internal employee who happens to be an information security professional and has an elevated level of access to a server system. Another vulnerability is an enabled USB port.
And the last concept we will talk about is an exploit. An exploit is a procedure, a piece of software, or a sequence of commands that takes advantage of a vulnerability to actually carry out an attack.
For example, say we have an enabled USB port on our customer databaseâ€""first vulnerabilityâ€""and we also have a disgruntled employeeâ€""second vulnerability.
Let's say that the employee decides to use a USB thumb drive to steal the customer database. This is an exploit. The employee used the vulnerability of the enabled USB port and their elevated permissions in order to steal the customer database.
Because security is a constant balancing act between convenience and protection, you will constantly be looking at ways you can mitigate risk and threats while also maintaining an acceptable level of ease of use.

However, by understanding the basic concepts of information security, you will have a much easier time assessing the risks to your systems and identifying the ways in which you can protect it.

1.1.3 Security Introduction Facts

Security is an ongoing process that includes assessing requirements, setting up organizational security systems, hardening and monitoring those systems, responding to attacks in progress, and deterring attackers. If you can summarize the fundamental concepts that underpin security functions, you can contribute more effectively to a security team. You must also be able to explain the importance of compliance factors and best practice frameworks in driving the selection of security controls and how departments, units, and professional roles within different types of organizations implement the security function.

This lesson covers the following topics:

- Security challenges
- Security control types
- Security roles and responsibilities

Security Challenges

In regards to information security, computers, and IT networks, modern-day security challenges include the following:

Challenge	Description
Sophisticated attacks	Sophisticated attacks are complex, making them difficult to detect and thwart. Sophisticated attacks: • Use common internet tools and protocols, making it difficult to distinguish an attack from legitimate traffic. • Vary their behavior, making the same attack appear differently each time.
Proliferation of attack software	A wide variety of attack tools are available on the internet, allowing anyone with a moderate level of technical knowledge to download the tools and run an attack.
Attack scale and velocity	The scale and velocity of an attack can grow to millions of computers in a matter of minutes or days due to its ability to proliferate on the internet. Because modern attacks are not limited to user interactions, such as using a floppy disk to spread an attack from machine to machine, the attacks often affect very large numbers of computers in a relatively short amount of time.

Security Control Types

Information security and cybersecurity assurance are met by implementing security controls. By identifying basic security control types, you will be better prepared to select and implement the most appropriate controls for a given scenario.

All controls are designed to fulfill three main goals: confidentiality, integrity, and availability.

- **Confidentiality** ensures that data is not disclosed to unauthorized persons.
- **Integrity** ensures that data is not modified or tampered with.
- **Availability** ensures the data is available when needed.

Security controls can be classified in different ways to fulfill the goals of your organization.

- Controls can be classified based on the way they are implemented. This includes oversight or managerial controls, operational controls that rely on people, technical or system-based controls, and, finally, non-technical physical controls such as alarms, locks, cameras, etc.
- Another method is to classify controls by the goal or function they perform. This involves controls that prevent attacks before they happen, detect attacks when they occur, and help correct and restore damage caused by attacks.
- Finally, there are controls to cover additional areas such as employee expectations, policies, and employment or disciplinary procedures. Other controls may not actually do anything but are designed to deter malicious actions. There are also times when standards or legal requirements mandate controls that should be used. If it is not possible to implement, an organization can sometimes replace that control with a replacement option that is as good or better than the original.

Security Roles and Responsibilities

You should also be able to describe how specific job roles and organizational structures can implement a comprehensive security program for organizations. IT professionals working in a role with security responsibilities must be competent in a wide range of disciplines, from network and application design to procurement and human resources (HR). The following activities might be typical of such a role:

- Participate in risk assessments and testing of security systems and make recommendations.
- Specify, source, install, and configure secure devices and software.
- Set up and maintain document access control and user privilege profiles.
- Monitor audit logs, review user privileges, and document access controls.
- Manage security-related incident response and reporting.
- Create and test business continuity and disaster recovery plans and procedures.
- Participate in security training and education programs.

The following units are often used to represent the security function within the organizational hierarchy.

A security operations center (SOC) is a location where security professionals monitor and protect critical information assets across other business functions, such as finance, operations, sales/marketing, etc. Because SOCs can be difficult to establish, maintain, and finance, they are usually employed by larger corporations, like a government agency or a healthcare company.

A security operations center (SOC) provides resources and personnel to implement rapid incident detection and response, plus oversight of cybersecurity operations. (Image © gorodenkoff 123RF.com.)

Network operations and cloud computing make ever-increasing use of automation through software code. Traditionally, software code would be the responsibility of a programming or development team. Separate development and operations departments or teams can lead to silos, where each team does not work effectively with the other.

Development and operations (DevOps) is a cultural shift within an organization to encourage much more collaboration between developers and systems administrators. By creating a highly orchestrated environment, IT personnel and developers can build, test, and release software faster and more reliably. DevSecOps extends the boundary to security specialists and personnel, reflecting the principle that security is a primary consideration at every stage of software development and deployment. This is also known as shift left, meaning that security considerations need to be made during requirements and planning phases, not grafted on at the end. The principle of DevSecOps recognizes this and shows that security expertise must be embedded into any development project. Ancillary to this is the recognition that security operations can be conceived of as software development projects. Security tools can be automated through code. Consequently, security operations need to take on developer expertise to improve detection and monitoring.

A dedicated computer incident response team (CIRT)/computer security incident response team (CSIRT)/computer emergency response team (CERT) is a single point of contact for the notification of security incidents. This function might be handled by the SOC, or it might be established as an independent business unit.

1.1.4 Security Job Roles (Lesson Video)

Transcript:

James Stanger

When it comes to the world of cyber security there are a lot of kinda continents available in that world. In other words, there are a lot of different jobs within the realm of cyber security. To tell us more about that we've got Brian Calkin. Brian, how you doin'?
Brian Calkin
I'm doing great, James. How are you?
James Stanger
Doing great, man. Doing great. Brian Calkin is the Chief Technology Officer for CyberWA. And Brian, tell us a bit more about CyberWA yourself. Let's start talking about the world of cyber security jobs that are available to folks.
Brian Calkin
Absolutely, yeah. So I've been in cyber security now for going on 20 years, various roles over the years I've had, to include all the way from a SOC analyst to a person that has built SOCs, run SOCs, led response teams, various management roles,executive roles. And as you mentioned, currently the Chief Technology Officer for a company called CyberWA where we are offering cyber protective services for high-net-worth individuals and celebrities.
James Stanger
So you know when it comes to putting a Security Operations Center together, more importantly you have to have workers at various tiers, various levels. Is a Security Operations Center analyst, a SOC analyst, a good first cyber security job?
Brian Calkin
I'd actually argue it's the best first cyber security job, but I can stand by that pretty strongly having been one, and having hired many and managed many of them over the years. I think that as folks are getting started in cyber security, and they may be not exactly sure where their passions might lie, whether they want to dive into penetration testing, or vulnerability assessments, or incident response, I think that you get enough exposure to each of those various individual sort of work items with being a SOC analyst. You just get this broad experience that you can apply later on in your career.
James Stanger
I've known quite a few beginning SOC analysts. They basically take tickets, as it were, oftentimes, right? And then they determine if they can handle it themselves, if it really is a big thing, and then escalate it. Is that, in general terms, what you're gonna do with that particular job role?

Brian Calkin
Absolutely, yeah. So generally the way it works is we will hire somebody, you know, either straight out of college, or maybe new to cyber security in general, as what we call an entry level or a tier one analyst. So these are the folks that are
getting the broadest experience in handling most of the, if not all of the inbound requests from customers, whether they be internal customers to your organization, or, you know, external customers if you're running an external shop. But yeah, fielding emails, fielding phone calls, and running down things like, you know, requests for analysis or requests for assistance. And then yeah, if they get into a bind or a tough spot where they've sort of hit the limits of what they know and can do, then they would escalate up to the tier two analyst.
James Stanger
You know, there are other job roles out there, you know, a pen tester for example, or security administrator. Let's talk about a couple of those real quick.
Brian Calkin
Yeah, sure. Those are always popular too, and folks, they like the pen testing roles, security admin roles, security engineer roles. So for instance a penetration tester would be somebody that is identifying vulnerabilities in a system, or a network, or a networkperimeter, and then trying to put on the role of the hacker or the black hat, and then try to exploit those vulnerabilities to try to get in, you know. And the purpose, of course, is to let the organization know they found this vulnerability and they were able to exploit it, versus a security engineer would be, so if a pen tester is playing offense, the engineer would be playing defense. The security engineer is preparing those systems to be as secure as possible as they're being deployed. Think, you know, deploying a new server and hardening it for best practice or per recommendations in order to make it as resilient as possible to a cyber attack.
James Stanger
Additional job roles can include things like, you know, a help desk analyst, or a vulnerability manager, things like that. But tell me a bit more about some of those.
Brian Calkin
Yeah, sure. Vulnerability assessment, vulnerability manager is another really popular one that, you know, I've worked with a number of those folks over the years. So these are the folks that are essentially doing things like, or could include running vulnerability scans, looking at various vulnerabilities that an organization might have within their environment, and then assessing, you know, what is the impact should this vulnerability get exploited, making sure the vulnerability can be patched, if it maybe can't be patched, and what else they could do to help mitigate the vulnerability. You know, is there some other mitigating factor in play they could apply to kind of close that hole, you know, if you will.
James Stanger
Brian, thank you so much for talking about just a few of the many job roles that are available within cyber security. Sure appreciate it, man.
Brian Calkin
Yeah, you're welcome. Thanks, James.

1.1.5 Practice Questions (Section Quiz)

q_sec_intro_cia_secp8

Which of the following are often identified as the three main goals of security? (Select three.)

Answers:

- ***Integrity**
- ***Confidentiality**
- Employees
- ***Availability**
- Policies
- Assets
- Non-repudiation

Explanation:

The acronym CIA refers to confidentiality, integrity, and availability in respect to security. These are often identified as the three main goals of any security-oriented task.

Non-repudiation provides validation of a message's origin.

Policies are the rules an organization implements to protect information.

Employees can be the most overlooked, yet most dangerous, threat agent because they have greater access to information assets than anyone on the outside trying to break in.

An asset is something that has value to a person or organization, such as sensitive information in a database.

q_sec_intro_cirt_secp8

A large multinational corporation has recently experienced a significant data breach. The breach was detected by an external cybersecurity firm, and the corporation's IT department was unable to prevent or detect the breach in its early stages.

The CEO wants to ensure that such a breach does not happen again and is considering several options to enhance the company's security posture.

Which of the following options would be the MOST effective in preventing and detecting future data breaches?

Answers:

- Hiring an external cybersecurity firm to conduct regular penetration testing.
- ***Implementing a dedicated Computer Incident Response Team (CIRT).**
- Increasing the budget for the IT department to purchase more advanced security software.
- Conducting regular cybersecurity training for all employees.

Explanation:

Implementing a dedicated Computer Incident Response Team (CIRT) is the most effective option. A CIRT is a group of experts who respond to security incidents. They have the skills and authority to respond quickly and effectively to security incidents, minimizing the impact and preventing further damage. This team would also be responsible for monitoring the company's network for signs of a breach, allowing them to detect and respond to incidents more quickly in the future.

Hiring an external cybersecurity firm to conduct regular penetration testing is a good practice, but it is not sufficient on its own. Penetration testing can identify vulnerabilities, but it does not provide continuous monitoring or incident response capabilities.

Increasing the budget for the IT department to purchase more advanced security software can be helpful, but software alone cannot fully protect a company from data breaches. Effective security requires a combination of technology, processes, and people.

Conducting regular cybersecurity training for all employees is important, but it is not enough to prevent and detect data breaches. Employees can help prevent breaches by following good security practices, but they cannot be expected to have the specialized skills needed to detect and respond to sophisticated attacks.

q_sec_intro_confidentiality_secp8

A user copies files from her desktop computer to a USB flash device and puts the device into her pocket.

Which of the following security risks is MOST pressing?

Answers:

- ***Confidentiality**
- Availability
- Non-repudiation
- Integrity

Explanation:

Confidentiality ensures that data is not disclosed to unintended persons. Removable media poses a big threat to confidentiality because it makes it easy to remove data and share it with unauthorized users.

Availability ensures that data is available when it is needed. Copying files to a server that includes malware could threaten the data's availability if the malware deletes or corrupts the data.

Integrity ensures that data is not modified or tampered with.

Non-repudiation provides validation of a message's origin.

q_sec_intro_devops_secp8

You are the Chief Information Security Officer (CISO) at a tech company. Your company is facing issues with silos between the development and operations teams, leading to inefficiencies and security vulnerabilities.

Which approach should you adopt to encourage collaboration and integrate security considerations at every stage of software development and deployment?

Answers:

- Implementing a new security policy
- Establishing a Security Operations Center (SOC)
- ***Adopting a Development and Operations (DevOps) approach**
- Outsourcing security to a third-party vendor

Explanation:

Adopting a Development and Operations (DevOps) approach is the correct answer. The DevOps approach encourages collaboration between developers and systems administrators, integrating security considerations at every stage of software development and deployment. This can help break down silos and improve both efficiency and security.

While implementing a new security policy can help improve security, it does not directly address the issue of silos between the development and operations teams.

A Security Operations Center (SOC) is a dedicated team that monitors and protects critical information assets across the organization. However, it does not directly address the issue of silos between the development and operations teams.

While outsourcing can be a viable option for some organizations, it does not directly address the issue of silos between the development and operations teams. Furthermore, it may not provide the same level of control and oversight as an integrated internal team.

q_sec_intro_integrity_secp8

Your computer system is a participant in an asymmetric cryptography system. You've created a message to send to another user. Before transmission, you hash the message and encrypt the hash using your private key. You then attach this encrypted hash to your message as a digital signature before sending it to the other user.

In this example, which protection does the hashing activity provide?

Answers:

- Confidentiality
- ***Integrity**
- Availability
- Non-repudiation

Explanation:

Hashing of any sort, including within a digital signature, provides data integrity.

Signing the message with the private key creates non-repudiation.

A digital signature activity, as a whole, does not provide protection for confidentiality because the original message is sent in cleartext.

No form of cryptography provides protection for availability.

q_sec_intro_managerial_controls_secp8

Which of the following is a method of implementing security controls?

Answers:

- ***Managerial controls**
- Financial controls
- Marketing controls
- Sales controls

Explanation:

Managerial controls is the correct answer. Managerial controls are administrative actions that define the organization's security posture through policy, guidelines, standards, procedures, and other forms of documentation. They provide a framework for operation and are essential for the organization's security program.

While financial controls are important in a business context, they are not a method of implementing security controls. Financial controls manage the accuracy and reliability of financial transactions and reporting, not the security of an organization's information systems.

Marketing controls are not a method of implementing security controls. They are methods used by marketing departments to analyze and measure their strategies and campaigns, not to secure an organization's information systems.

Sales controls are not a method of implementing security controls. They are methods used by sales departments to manage and track sales activities, not to secure an organization's information systems.

q_sec_intro_scale_and_velocity_secp8

Which of the following security challenges refers to the rapid and broad spread of an attack, often affecting a large number of computers in a relatively short amount of time?

Answers:

- Sophisticated attacks
- Proliferation of attack software
- ***Attack scale and velocity**
- Data encryption

Explanation:

Attack scale and velocity is the correct answer. It refers to the scale and speed of an attack, which can grow to millions of computers in a matter of minutes or days due to its ability to proliferate on the internet.

Sophisticated attacks are complex attacks that are difficult to detect and thwart. They use common internet tools and protocols, making it difficult to distinguish an attack from legitimate traffic. They also vary their behavior, making the same attack appear differently each time. However, this option does not specifically refer to the speed and scale of an attack.

Proliferation of attack software refers to the wide variety of attack tools available on the internet, allowing anyone with a moderate level of technical knowledge to download the tools and run an attack. While this can contribute to the scale and velocity of an attack, it is not the same thing.

While data encryption is a crucial aspect of cybersecurity, it is not a security challenge. Instead, it is a method used to protect data from unauthorized access.

q_sec_intro_soc_secp8

You are the Chief Information Security Officer (CISO) at a large corporation. Your company is expanding rapidly and the complexity of managing security across different business functions is increasing.

You need a dedicated team to monitor and protect critical information assets across the organization.

Which of the following would be the MOST effective solution?

Answers:

- Implementing a new security policy
- ***Establishing a Security Operations Center (SOC)**
- Hiring more IT staff
- Outsourcing security to a third-party vendor

Explanation:

Establishing a Security Operations Center (SOC) is the correct answer. A SOC is a dedicated team that monitors and protects critical information assets across the organization. It provides resources and personnel to implement rapid incident detection and response, plus oversight of cybersecurity operations.

While implementing a new security policy can help improve security, it does not provide the dedicated monitoring and protection needed for critical information assets across different business functions.

While hiring more IT staff can help manage the increased workload, it does not provide the dedicated monitoring and protection needed for critical information assets across different business functions.

While outsourcing can be a viable option for some organizations, it may not provide the same level of control and oversight as a dedicated internal team like a SOC.

q_sec_intro_sophisticated_attacks_secp8

You are the head of the cybersecurity team at a large corporation. You notice an increase in network traffic that appears to be legitimate but is causing a slowdown in your systems.

Upon further inspection, you find that the traffic patterns vary each time, making it difficult to distinguish from normal traffic.

What type of security challenge are you MOST likely facing?

Answers:

- Proliferation of attack software
- Attack scale and velocity
- ***Sophisticated attack**
- Data breach

Explanation:

A sophisticated attack is the correct answer. Sophisticated attacks are complex and often use common internet tools and protocols, making them difficult to distinguish from legitimate traffic. They also vary their behavior, making the same attack appear differently each time, which aligns with the observed traffic patterns.

Proliferation of attack software refers to the wide availability of attack tools on the internet, which allows anyone with moderate technical knowledge to download the tools and run an attack. While this could potentially cause an increase in network traffic, it does not account for the varying traffic patterns observed.

Attack scale and velocity refers to the rapid and widespread proliferation of an attack, often affecting a large number of computers in a short amount of time. While this could cause a slowdown in systems, it does not account for the varying traffic patterns observed.

A data breach refers to an incident where information is accessed without authorization. While a data breach could potentially result from the security challenge faced, it does not in itself explain the varying traffic patterns observed.

q_sec_intro_technical_control_secp8

You are the Chief Information Security Officer (CISO) at a large corporation. You have been tasked with implementing a new security control to protect sensitive customer data.

The control must be able to automatically detect and prevent unauthorized access to the data.

Which type of control should you implement?

Answers:

- Managerial control
- Operational control

- ***Technical control**
- Physical control

Explanation:

Technical control is the correct answer. Technical controls involve the use of technology to reduce vulnerabilities. This includes controls that can automatically detect and prevent unauthorized access, such as intrusion detection systems, firewalls, and access control mechanisms.

Managerial controls are administrative actions that define the organization's security posture through policy, guidelines, standards, procedures, and other forms of documentation. While they are crucial for setting the overall direction of an organization's security, they do not automatically detect and prevent unauthorized access to data.

Operational controls are the day-to-day procedures and mechanisms that protect an organization's assets. While they can include procedures for detecting and preventing unauthorized access, they do not typically do this automatically.

Physical controls involve measures to prevent physical access to assets, such as locks, fences, and security guards. While they are crucial for protecting physical assets, they do not automatically detect and prevent unauthorized access to digital data.

1.2 Security Controls

As you study this section, answer the following questions:

- What are the three types of control categories?
- What are preventative controls?
- What is the difference between corrective and compensating controls?

The key terms for this section include:

Term	Definition
Security control	A technology or procedure put in place to mitigate vulnerabilities and risk and to ensure the confidentiality, integrity, and availability (CIA) of information.
Managerial	A category of security control that provides oversight of information systems.
Operational	A category of security control that is implemented by people.
Technical	A category of security control that is implemented as a system.
Physical	A category of security control that is implemented by hardware used to deter or detect, such as as alarms, gateways, locks, lighting, and security cameras.
Preventive	A type of security control that acts before an incident to eliminate or reduce the likelihood that an attack can succeed.

Access control lists (ACLs)	The collection of access control entries (ACEs) that determines which subjects (user accounts, host IP addresses, and so on) are allowed or denied access to the object and the privileges given (read-only, read/write, and so on).
Detective	A type of security control that acts during an incident to identify or record that it is happening.
Corrective	A type of security control that acts after an incident to eliminate or minimize its impact.
Directive	A type of control that enforces a rule of behavior through a policy or contract.
Deterrent	A type of security control that discourages intrusion attempts.
Compensating	A security measure that takes on risk mitigation when a primary control fails or cannot completely meet expectations.
Chief Information Officer (CIO)	A company officer with the primary responsibility of managing information technology assets and procedures.
Chief Technology Officer (CTO)	A company officer with the primary role of making effective use of new and emerging computing platforms and innovations.
Chief Security Officer (CSO)	Typically, the job title of the person with overall responsibility for information assurance and systems security.
Information Systems Security Officer (ISSO)	Organizational role with technical responsibilities for implementation of security policies, frameworks, and controls.

This section helps you prepare for the following certification exam objectives:

Exam	Objective

CompTIA Security+ SY0-701	1.1 Compare and contrast various types of security controls.
	• Categories
	  ○ Technical
	  ○ Managerial
	  ○ Operational
	  ○ Physical
	• Control types
	  ○ Preventive
	  ○ Deterrent

	○ Detective ○ Corrective ○ Compensating ○ Directive

1.2.1 Control Categories and Types (Lesson Video)

Transcript:

In this video, I'll discuss security control categories and types. As a security professional, your job is to protect the company's assets and business. This means that you're there to prevent hazardous events or to minimize their damage. Let's get started.

Managerial controls consist of management techniques and administrative procedures. These can include security policies, hiring policies, disaster recovery plans, or DPRs, and business continuity plans, or BCPs. You should always include written plans for how and when to escalate events and when you need to consult outside help.
Operational controls are ones that the security team performs everyday. These might include reviewing network monitoring data, ensuring that security cameras are working, and requiring visitors to sign in.
Technical controls are based around software, applications, and security appliances. These controls vary greatly by company. Some examples you might see in your line of work are IDSs, IPSs, access control apps, and ASAs.
We use preventative controls for security breaches, but you might see these tools used with other control types as well. The easiest preventative control is an Advance Network Appliance, which is sometimes also called an Adaptive Security Appliance, or ASA. This is basically a firewall and router combination that's capable of hosting IDSs and IPSs. A less expensive preventative control is a simple updated antivirus, considering that these have improved drastically over the years. Office access control is also an excellent preventative control, especially if you're using biometrics.
Detective controls inform the security team of an event that's occurring or provide them with logs and artifacts to them help investigate the event further. Examples would be network monitoring applications, log collectors, real-time monitoring alerts, and intrusion detection systems, or IDSs.
Corrective controls are those that attempt to fix any damage caused by an event. These tools work during and after the course of the event. Think of this as a form of risk mitigation. For example, an intrusion prevention system, or IPS, is designed to intercept packets that are potentially malicious and either drop or isolate them. Another example is endpoint protection, which works to stop malicious data by looking at its signature or behavior.
The deterrent control type discourages malicious actors from trying to breach a network. The more deterrents you have, the less likely it is that anyone will try. These could include internal security
policies, access-protected doors for a server room, entry-point access restriction, biometric sensors, man traps, security cameras, security training, and security guards. Remember, the stronger the deterrents, the less likely it is that a breach occurs.
Physical deterrents keep unauthorized people from physically accessing a company's assets. So locked doors, proximity cards, fences, cameras, and guards are all ways to physically protect your network. Motion detectors for after-hours monitoring is another example.
Please note that device management is often overlooked by companies. With the prevalence of mobile devices, your company should be able to remotely wipe any devices that are lost or stolen. Let's look at some scenarios.
Let's say that a biometric thumbprint scanner has been installed in the lobby of your building. It requires everyone to scan their thumb to gain access. A malicious actor tries to enter, but their print doesn't match. An access-denied alert is flashed on the screen, and the IT team is fully aware of what's happening. Usually, the imposter doesn't stay around to be questioned!
Another common ploy is for an imposter to try and take advantage of a person's kindness. In this case, an imposter tries to gain entrance from a legitimate employee's proximity badge by claiming to have forgotten theirs. Hopefully, the employee remembers their security training and politely tells the imposter, "No."
That's it for this lesson. In this lesson, we learned about control categories as well as control types. Categories include managerial, operational, and technical. The security control types we learned about are preventative, corrective, deterrent, and physical. You should use all of these tools together to help you create a secure network.

1.2.2 Control Categories and Types Facts

Information security and cybersecurity assurance are met by implementing security controls. By identifying basic security control types, you will be better prepared to select and implement the most appropriate controls for a given scenario. You should also be able to describe how specific job roles and organizational structures can implement a comprehensive security program for organizations.

This lesson covers the following topics:

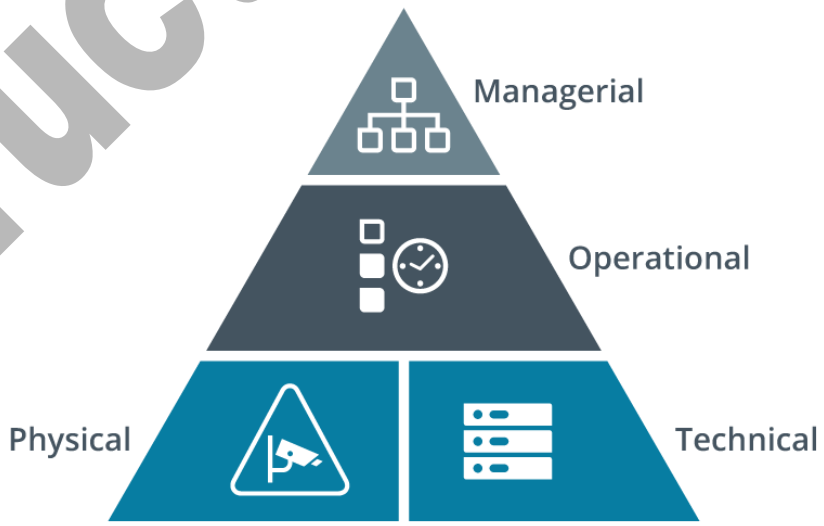
- Security control categories
- Security control functional types

Security Control Categories

Information and cybersecurity assurance usually takes place within an overall process of business risk management. Implementation of cybersecurity functions is often the responsibility of the IT department. There are many ways of thinking about how IT services should be governed to fulfill overall business needs. Some organizations have developed IT service frameworks to provide best practice guides for implementing IT and cybersecurity. These frameworks can shape company policies and provide checklists of procedures, activities, and technologies that represent best practices. Collectively, these procedures, activities, and tools can be referred to as security controls.

A security control is designed to give a system or data asset the properties of confidentiality, integrity, availability, and non-repudiation. Controls can be divided into four broad categories based on the way the control is implemented:

- **Managerial** — the control gives oversight of the information system. Examples could include risk identification or a tool allowing the evaluation and selection of other security controls.
- **Operational** — the control is implemented primarily by people. For example, security guards and training programs are operational controls.
- **Technical** — the control is implemented as a system (hardware, software, or firmware). For example, firewalls, antivirus software, and OS access control models are technical controls.
- **Physical** — controls such as alarms, gateways, locks, lighting, and security cameras that deter and detect access to premises and hardware are often placed in a separate category from technical controls.



Categories of security controls

Although it uses a different scheme, be aware of how the National Institute of Standards and Technology (NIST) classifies security controls (csrc.nist.gov/publications/detail/sp/800-53/rev-5/final).

For example, as of NIST 800-53 rev 4, the class designations of technical, operational, and managerial were removed from the control families list. Instead, they were redefined as properties of individual controls within a family. They are included to help familiarize learners with the basic concepts presented in 800-53 and due to the continued use of this terminology by many organizations and publications. Be aware that terminology usage and practice are always evolving.

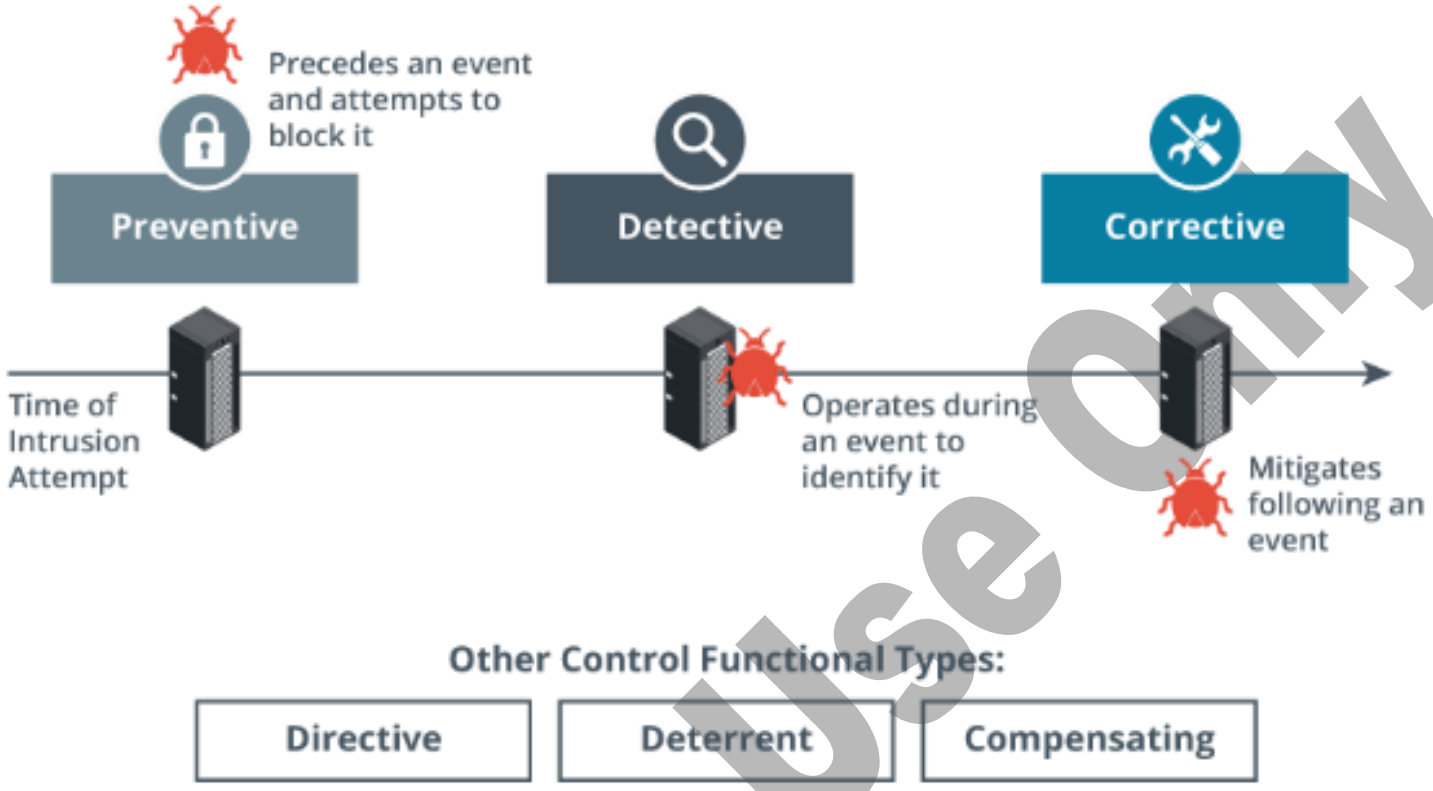
Security Control Functional Types

As well as a category, a security control can be defined according to the goal or function it performs:

- **Preventive** — the control acts to eliminate or reduce the likelihood that an attack can succeed. A preventive control operates before an attack can take place. Access control lists (ACLs) configured on firewalls and file system objects are preventive-type technical controls. Antimalware software acts as a preventive control by blocking malicious processes from executing.
- **Detective** — the control may not prevent or deter access, but will identify and record an attempted or successful intrusion. A detective control operates during an attack. Logs provide one of the best examples of detective-type controls.
- **Corrective** — the control eliminates or reduces the impact of a security policy violation. A corrective control is used after an attack. A good example is a backup system that restores data damaged during an intrusion. Another example is a patch management system that eliminates the vulnerability exploited during the attack.

While most controls can be classed functionally as preventive, detective, or corrective, a few other types can be used to define other cases:

- **Directive** — the control enforces a rule of behavior, such as a policy, best practice standard, or standard operating procedure (SOP). For example, an employee's contract will set out disciplinary procedures or causes for dismissal if they do not comply with policies and procedures. Training and awareness programs can also be considered as directive controls.
- **Deterrent** — the control may not physically or logically prevent access, but it psychologically discourages an attacker from attempting an intrusion. This could include signs and warnings of legal penalties against trespass or intrusion.
- **Compensating** — the control is a substitute for a principal control, as recommended by a security standard. It affords the same (or better) level of protection but uses a different methodology or technology.



Functional types of security controls. (Images © 123RF.com.)

A security policy is a formalized statement that defines how security will be implemented within an organization. It describes the means the organization will take to protect the confidentiality, availability, and integrity of sensitive data and resources.

The implementation of a security policy to support the goals of the CIA triad might be very different for a school, a multinational accountancy firm, or a machine tool manufacturer. However, each of these organizations, or any other organization (in any sector of the economy, whether profit-making or non-profit-making), should have the same interest in ensuring that its employees, equipment, and data are secure against attack or damage. An organization that develops security policies and uses framework-based security controls has a strong security posture.

As part of the process of adopting an effective organizational security posture, employees must be aware of their responsibilities. The structure of security responsibilities will depend on the size and hierarchy of an organization, but these roles are typical.

- Overall responsibility for the IT function lies with a Chief Information Officer (CIO) . This role might also have direct responsibility for security. Some organizations will also appoint a Chief Technology Officer (CTO) , with more specific responsibility for ensuring the effective use of new and emerging IT products and solutions to achieve business goals.
- In larger organizations, internal responsibility for security might be allocated to a dedicated department run by a Chief Security Officer (CSO) or Chief Information Security Officer (CISO).
- Managers may have responsibility for a domain, such as building control, web services, or accounting.
- Technical and specialist staff have responsibility for implementing, maintaining, and monitoring the policy. Security might be made of a core competency of systems and network administrators, or there may be dedicated security administrators. One such job title is Information Systems Security Officer (ISSO) .
- Nontechnical staff have the responsibility of complying with policy and with any relevant legislation.
- External responsibility for security (due care or liability) lies mainly with directors or owners, though again, it is important to note that all employees share some measure of responsibility.

NIST's National Initiative for Cybersecurity Education (NICE) categorizes job tasks and job roles within the cybersecurity industry (gov/itl/applied-cybersecurity/nice/nice-framework-resource-center).

1.2.3 Security Control and Framework Types

1.2.4 Practice Questions (Section Quiz)

q_ctrl_cattypes_categories_secp8

Which of the following are control categories? (Select three.)

Answers:

- ***Managerial**
- Preventative
- ***Operational**
- Deterrent
- ***Technical**
- Compensating
- Physical

Explanation:

Control categories are:

- Managerial controls (consist of management techniques and administrative procedures)
- Operational controls (performed everyday by the security team)
- Technical controls (based around software, applications, and security appliances)

The remaining items are all control types. Control types consist of different strategies to prevent, detect, mitigate, and correct any network breach.

q_ctrl_cattypes_compensating_01_secp8

Which of the following BEST describes compensating controls?

Answers:

- ***Partial control solution that is implemented when a control cannot fully meet a requirement.**
- Monitors network activity and informs the security team of a potential security event.
- Attempts to fix any controls that aren't working properly.
- Discourages malicious actors from attempting to breach a network.

Explanation:

Compensating controls are a partial control solution that is implemented when a control cannot fully meet a requirement.

Detective controls monitor network activity and inform the security team of a potential security event.

Corrective controls attempt to fix any controls that aren't working properly.

Deterrent controls discourage malicious actors from attempting to breach a network.

q_ctrl_cattypes_compensating_02_secp8

The IT director at a financial institution focuses on implementing compensating managerial controls to augment the institution's existing security framework.

If a mandated control cannot be put into place, which of the following compensating controls should an analyst recommend as a sufficient substitute?

Answers:

- ***Isolating a critical system that cannot be patched.**
- Regular employee training on cybersecurity best practices.
- Using biometric access controls on all company systems.
- An automated system that scans and patches software vulnerabilities.

Explanation:

In a scenario where the analyst cannot patch a critical system due to operational reasons, isolating it from the network can serve as a compensating control. This offers an equivalent level of protection by ensuring potential cyber threats cannot reach the system.

While employee training is an important part of any organization's security controls, it classifies as an operational control more than a managerial one.

Biometric access controls are technical controls, not managerial ones. They use hardware and software to restrict access to systems and data.

While an automated system for scanning and patching software vulnerabilities is a critical part of any organization's cybersecurity strategy, it is a technical control, not a managerial control.

q_ctrl_cattypes_compensating_03_secp8

After finding some of the company's confidential data on the internet, a software team is drafting a policy on vulnerability response and remediation.

What remediation practice refers to measures put in place to mitigate the risk of a vulnerability when the team cannot directly eliminate it?

Answers:

- ***Compensating controls**
- Patching
- Insurance
- Segmentation

Explanation:

Compensating controls refer to measures put in place to mitigate the risk of a vulnerability when security teams cannot directly eliminate it or when direct remediation is not immediately possible.

Patching is one of the most straightforward and effective remediation practices. It involves applying updates and patches to software or systems to fix known vulnerabilities.

Insurance provides financial protection in case of a security breach resulting from a vulnerability and is important in a comprehensive risk management strategy, complementing technical controls with financial risk transfer.

Segmentation involves dividing a network into separate pieces to contain potential security breaches.

q_ctrl_cattypes_compensating_04_secp8

An organization changes its security posture after a breach and wants to enhance encryption by putting meaures in place to mitigate risk exposures that cannot be directly eliminated by the cyber security team.

What type of control is being observed in this situation?

Answers:

- ***Compensating**
- Technical
- Administrative
- Detective

Explanation:

Compensating controls refer to measures put in place to mitigate the risk of a vulnerability when security teams cannot directly eliminate it or when direct remediation is not immediately possible, such as additional monitoring or enhanced encryption.

The security manager would implement a technical control in operating systems, software, and security appliances, with examples including an access control list (ACL) or an intrusion prevention system (IPS).

The security manager uses administrative security controls to dictate behavior through guidelines, policies, and procedures.

While a detective control may not deter or prevent access, it records and identifies any successful or attempted intrusion, exemplified by a security camera system.

q_ctrl_cattypes_corrective_01_secp8

A company moved its office supplies to another room and instituted a new security system for entry. The company implemented this after a recent server outage.

What category of security control BEST describes the function of this recent implementation?

Answers:

- ***Corrective**
- Preventive
- Detective
- Operational

Explanation:

Corrective controls eliminate or reduce the impact of a security policy violation. A corrective control occurs after an attack. For this scenario, segregating server space access from common access would be corrective.

Preventive controls eliminate or reduce the likelihood that an attack can succeed. The company implements this control to avert a potential incident from occurring.

Detective controls may not prevent or deter access, but they will identify and record an attempted or successful intrusion. A security camera would be a type of detective control.

Operational controls involve people, such as hiring security guards and performing training programs.

q_ctrl_cattypes_corrective_02_secp8

After encountering a cyber attack, an organization uses a monitoring solution that automatically restarts services after it has detected the system has crashed.

What type of functional security control is the company implementing?

Answers:

- ***Corrective**
- Compensating
- Technical
- Managerial

Explanation:

Corrective control actively responds to an incident, fixes it, and prevents it from happening again. Antivirus software exemplifies a corrective control.

Rather than preventing an attack, a compensating control actively restores the functionality of systems via alternative methods, such as using a backup.

The implementation of technical controls occurs in operating systems, software, and security appliances such as access control lists (ACLs) or intrusion prevention systems (IPS).

Managerial security controls actively shape behavior through policies, procedures, and guidance. A fair use policy serves as an example of such a control.

q_ctrl_cattypes_detective_secp8

The chief security officer (CSO) at a financial organization wants to implement additional detective security controls.

Which of the following would BEST represent this type of control?

Answers:

- ***Installation of surveillance camera.**
- Enforcement of access control mechanisms.
- Implementation of biometric authentication systems.
- Performing regular system backups.

Explanation:

Surveillance cameras are physical controls that act as detective mechanisms, helping to identify unauthorized access or activities within the monitored area.

While it is an important security measure, enforcing access control mechanisms primarily serves as a preventive control. For example, it prevents unauthorized physical access but does not detect issues or breaches actively.

Although a biometric authentication system is an important control, it primarily serves as a preventive control. Biometric authentication prevents unauthorized access by ensuring verified individuals can access certain areas or data, but it does not actively detect breaches or security incidents.

Regular system backups are generally a corrective control that does not detect issues. Instead, they provide a means to recover after a security incident.

q_ctrl_cattypes_deterrent_01_secp8

Which type of control is used to discourage malicious actors from attempting to breach a network?

Answers:

- Detective
- Physical
- Preventative
- ***Deterrent**

Explanation:

The deterrent control type discourages malicious actors from trying to breach a network. The more deterrents are implemented, the less likely it is that anyone tries. These could include internal security policies, access-protected doors for a server room, entry-point access restriction, biometric sensors, man traps, security cameras, security training, and security guards.

Detective controls monitor network activity and inform the security team of a potential security event. Detective controls also log activities and provide artifacts to help investigate the event. Intrusion detection systems are an example of detective controls.

Physical deterrents keep unauthorized people from physically accessing a company's assets. Locked doors, proximity cards, fences, cameras, and guards are all ways to physically protect a network.

Preventative controls, such as an IPS, are used to prevent security breaches.

q_ctrl_cattypes_deterrent_02_secp8

A manufacturing company is looking to enhance its security measures by implementing deterrent controls in its facility, specifically the server room.

Which of the following options would be MOST effective?

Answers:

- ***Placing visible signs indicating surveillance and severe penalties for unauthorized entry.**

- Installing a network-connected smoke detector system in the server room.
- Applying reflective window film to the server room windows.
- Introducing a key control system for office desks.

Explanation:

Placing visible signs indicating surveillance and severe penalties for unauthorized entry is an example of a physical control. This kind of deterrence can discourage unauthorized physical access by setting clear consequences.

Installing a network-connected smoke detector system in the server room is a physical control, but it's designed to detect fire hazards, not deter unauthorized access.

Applying reflective window film to the server room windows is a physical control aimed at enhancing privacy, but it doesn't deter unauthorized access once inside the building.

Introducing a key control system for office desks is a physical control, but it's more relevant for securing individual workstations and personal belongings than deterring unauthorized access to a server room.

q_ctrl_cattypes_deterrent_03_secp8

A user in a company wants a new USB flash drive. Rather than requesting one through the proper channel, the user obtains one from one of the company's storage closets.

Upon approaching the closet door, the user notices a warning sign indicating cameras are in use.

What is the control objective of the observed sign?

Answers:

- ***Deterrent**
- Preventive
- Detective
- Corrective

Explanation:

A deterrent control may not physically or logically prevent access, but psychologically, it discourages an attacker from attempting an intrusion. A warning sign is an example of a deterrent control.

A preventive control physically or logically restricts unauthorized access. A system password and physical door lock are examples of preventive controls.

A detective control may not prevent or deter access, but it will identify and record any attempted or successful intrusion. A security camera system is an example of a detective control.

A corrective control responds to and fixes an incident. It may also prevent the reoccurrence of the incident. Antivirus software is an example of a corrective control.

q_ctrl_cattypes_directive_01_secp8

The head of IT security at a financial institution is working to enhance the directive controls in place within the company.

Which of the following should the institution implement?

Answers:

- ***Building access procedures**
- Biometric access control systems
- Intrusion detection systems (IDS)
- Closed-circuit television surveillance cameras

Explanation:

Building access procedures serve as an example of directive controls. They provide guidance and direction on the steps for gaining access to the building, helping to achieve the desired security outcome.

Biometric access control systems primarily function as technical and physical controls and do not serve as directive controls. They control access to physical or digital resources using biological characteristics like fingerprints or retinal scans.

Intrusion detection systems typically fall under the detective control category. While they can identify potentially harmful activities within a network, they do not offer guidance or direction.

Closed-circuit television surveillance cameras, which function primarily as physical controls, monitor and detect unauthorized access or activity. Although they can act as deterrents, they do not get classified as directive controls.

q_ctrl_cattypes_directive_02_secp8

The security operations manager of a multinational corporation focuses on enhancing directive operational controls.

Which of the following should the manager implement?

Answers:

- ***User awareness and training programs.**
- Firewall to block unauthorized network traffic.
- Surveillance cameras installed around the premises.
- Regular vulnerability assessments using automated tools.

Explanation:

User awareness and training programs are examples of directive operational controls. These controls are about guiding behavior towards specific outcomes, such as improving security awareness and adherence to protocols.

A firewall is a preventive control that serves to block unauthorized network traffic. Despite its importance, it doesn't guide behavior and therefore is not a directive control.

Surveillance cameras serve to monitor and detect potential security incidents. While they contribute to overall security, they do not guide behavior and are not directive controls.

Regular vulnerability assessments help in identifying potential security weaknesses. Although critical, they do not guide behavior, thus they are not considered directive controls.

q_ctrl_cattypes_directive_03_secp8

An information technology manager conducted an audit of the company's support tickets. The manager noticed a trend with the tickets, where the majority were for new computer setups.

What security control function would the manager's implementation of a new standard operating procedure have?

Answers:

- Compensating
- Deterrent
- ***Directive**
- Corrective

Explanation:

A directive control enforces a rule of behavior, such as a policy, best practice standard, or standard operating procedure (SOP).

Compensating controls are a substitute for a principal control, as recommended by a security standard, and afford the same (or better) level of protection. However, they use a different methodology or technology.

Deterrent controls may not physically or logically prevent access, but it psychologically discourages an attacker from attempting an intrusion. Deterrent controls could include signs and warnings of legal penalties against trespass or intrusion.

Corrective controls eliminate or reduce the impact of a security policy violation. A corrective control is used after an attack. A good example is a backup system that restores data that was damaged during an intrusion.

q_ctrl_cattypes_managerial_secp8

Which type of control makes use of policies, DPRs, and BCPs?

Answers:

- Operational
- Technical
- ***Managerial**
- Preventative

Explanation:

Managerial controls consist of management techniques and administrative procedures. These can include security policies, hiring policies, disaster recovery plans (DPRs), and business continuity plans (BCPs).

Operational controls are ones that the security team performs daily.

Technical controls are based around software, applications, and security appliances.

Preventative controls, such as an IPS, are used to prevent security breaches.

q_ctrl_cattypes_operational_secp8

An acceptable use policy requires the system to encrypt confidential information while in transit. All employees must use secure email when exchanging proprietary information with external vendors.

Which of the following describes this type of acceptable use policy?

Answers:

- ***Operational**
- Managerial
- Technical
- Preventive

Explanation:

Operational controls like this acceptable use policy focus on procedures and responsibilities that are well defined and executed by people. They help to ensure the security of an organization's day-to-day operations.

Managerial controls establish strategies, goals, and objectives for an organization's overall security program. They often include risk assessment and the review of security controls.

Technical controls involve the use of technology to control user access and protect information systems. They include network and system monitoring, firewalls, and intrusion detection systems.

Preventive controls are proactive measures designed to stop potential security incidents from happening. Examples include firewall configurations, user access controls, and security awareness training.

q_ctrl_cattypes_physical_01_secp8

When setting up a new server room for sensitive data storage, a tech company seeks to enhance preventive measures against unauthorized access.

Which measure would be MOST effective for this purpose?

Answers:

- ***Physical security**
- Video surveillance
- Server encryption
- Intrusion detection system (IDS)

Explanation:

Physical security is the first line of defense against unauthorized access to a server room. Physical security can include locked doors, access control systems, and security guards.

Although video surveillance offers a potent deterrent, its principal function is reactive rather than preventive. However, video surveillance does not preemptively stave off unauthorized access.

Server encryption primarily pertains to digital breaches and does not extend its protective purview to inhibit physical trespassing into a server room.

Although an IDS is invaluable for detecting digital intrusions, its capabilities do not traverse into the physical realm to avert unauthorized access to server rooms.

q_ctrl_cattypes_physical_02_secp8

After a recent server outage, the company discovered that an employee accidentally unplugged the power cable from the server while grabbing some office supplies from the nearby shelf.

What security control did the company lack that led to the server outage?

Answers:

- Managerial
- Technical
- Operational
- ***Physical**

Explanation:

Physical controls such as alarms, gateways, locks, lighting, and security cameras deter and detect access to premises.

Managerial controls provide oversight of the information system. Examples could include risk identification or a tool allowing the evaluation and selection of other security controls.

Technical controls are the implementation of a system, such as hardware, software, or firmware. For example, firewalls, antivirus software, and OS access control models are technical controls. For the server's security, segregating that equipment from normal employee access is important.

Operational controls are implemented primarily by people. For example, security guards and training programs are operational controls.

q_ctrl_cattypes_preventive_01_secp8

Which of the following is an example of a preventative control type?

Answers:

- ***An advanced network appliance**
- Real-time monitoring alerts
- Intrusion detection systems
- Network monitoring applications

Explanation:

The easiest prevention control is an advanced network appliance, which is sometimes called an adaptive security appliance (ASA).

Examples of detective controls are intrusion detection systems (ISPs), network monitoring applications, collectors logs, and real-time monitoring alerts.

q_ctrl_cattypes_preventive_02_secp8

A company installed a new locking cabinet in the computer room to hold extra flash drives and other supplies.

Which type of security control did the company configure?

Answers:

- ***Preventive**
- Compensating
- Containment
- Deterrent

Explanation:

A preventive control physically or logically restricts unauthorized access. A system password and physical door lock are examples of preventive controls.

Rather than preventing an attack, a compensating control actively restores the functionality of systems via alternative methods, such as using a backup.

Containment does not refer to a security control type; it refers to a step in the incident management lifecycle for handling a threat.

A deterrent control may not physically or logically prevent access, but psychologically, it discourages an attacker from attempting an intrusion. For example, a warning sign is a deterrent control.

q_ctrl_cattypes_security_control_secp8

After an unauthorized access incident in the server room over the weekend, the IT department of a company decides to implement new security controls to deter similar future incidents.

Which of the following should they implement?

Answers:

- ***Placing visible signs indicating surveillance and severe penalties for unauthorized entry**
- Installing a network-connected smoke detector system in the server room
- Applying reflective window film to the server room windows
- Introducing a key control system for office desks

Explanation:

Placing visible signs indicating surveillance and severe penalties for unauthorized entry is an example of a physical control. This kind of deterrence can discourage unauthorized physical access by setting clear consequences.

Installing a network-connected smoke detector system in the server room is a physical control, but it's designed to detect fire hazards, not deter unauthorized access.

Applying reflective window film to the server room windows is a physical control aimed at enhancing privacy, but it doesn't deter unauthorized access once inside the building.

Introducing a key control system for office desks is a physical control, but it's more relevant for securing individual workstations and personal belongings than deterring unauthorized access to a server room.

q_ctrl_cattypes_technical_01_secp8

Given the need to prioritize cost-effective solutions for enhancing the company's cybersecurity posture, a global corporation's chief security officer (CSO) considers implementing technical controls over physical controls.

Which of the following options is a technical control?

Answers:

- ***Setting up a network intrusion detection system**
- Implementing a risk identification tool
- Conducting employee cybersecurity training
- Installing a building access control system

Explanation:

Setting up a network intrusion detection system is an example of a technical control. It involves hardware and software systems specifically designed to monitor and control the network's security, thus serving as a cost-effective solution for improving the cybersecurity posture.

A risk identification tool falls under the category of managerial controls. These controls oversee the information system and aid in selecting and implementing other security controls.

Employee cybersecurity training is an operational control. Operational controls are primarily human-centric and focus on procedures and responsibilities to maintain the security of the organization.

Installing a building access control system is a physical control. Physical controls manage access to premises and hardware, often incurring higher implementation and maintenance costs compared to technical controls.

q_ctrl_cattypes_technical_02_secp8

As part of enhancing its data protection strategy, a corporation's IT manager aims to ensure defense-in-depth by integrating a technical control alongside existing managerial and operational controls.

Which measure BEST exemplifies a technical security control according to the classification scheme?

Answers:

- ***Setting up a network intrusion detection system**
- Implementing a risk identification tool
- Conducting employee cybersecurity training
- Installing a building access control system

Explanation:

Intrusion detection systems represent a technical control involving hardware and software systems specifically designed to monitor and control the network's security. Network intrusion detection systems are naturally automated and technical, making this the best example of a technical control in the options given.

Implementing a risk identification tool falls under the category of managerial controls. These types of controls oversee the information system.

Conducting employee cybersecurity training is an operational control. Operational controls are primarily people-oriented.

Installing a building access control system is a physical control. Physical controls are measures that deter and detect access to premises and hardware.

q_ctrl_cattypes_technical_03_secp8

A company finds that employees are accessing streaming websites that are not being monitored for malware or viruses.

Which type of control can the network administrator implement to protect the system and keep the employees from viewing unapproved sites?

Answers:

- ***Technical**
- Operational
- Detective
- Corrective

Explanation:

A technical security control includes hardware or software mechanisms used to protect assets. Additionally, antivirus software, firewalls, and intrusion detection systems are examples of technical controls.

Operational security control characterizes a tangible item, preventing or detecting unauthorized access to physical spaces, systems, and assets.

A detective control identifies when incidents or vulnerabilities have occurred. For example, auditing and monitoring would be detective controls.

Corrective control actively responds to an incident, fixes it, and prevents it from happening again. Antivirus software exemplifies a corrective control.

1.3 Use the Simulator

As you study this section, answer the following questions:

- How do I complete simulation labs in this course?
- What features have been simulated in this environment?
- How will getting acquainted with the simulation environment help me acquire the necessary skills?

In this section, you will learn to:

- Read simulated component documentation and view components to make appropriate choices to meet the scenario
- Add and remove simulated computer components
- Change views and add simulated components
- Use the zoom feature to view additional image details
- Use the simulation interface to identify where simulated cables connect to the computer
- Attach simulated cables
- Configure a security appliance
- Install a security appliance

Key terms for this section include the following:

Term	Definition
Lab simulator	The lab simulator is a LabSim learning tool that presents a virtual environment that you can manipulate like an actual environment.
Lab tasks	The tasks necessary to complete the lab.
Navigation bar	A lab simulation feature used to change to a new location, such as a building, floor, or office.
Shelf	An area that contains hardware components that may be used in the simulation.
Exhibits	Additional information about the simulation environment that may be useful in completing the lab.

1.3.1 Use the Simulator (Demo Video)

Transcript:

TestOut's lab activities are key to your training. In this demonstration, I'm going to show you the components of the Lab Simulator so that you can successfully complete the activities in this course.

Some labs start out with an overview of the office. We'll talk about that a bit more later, but first, let's click on Hardware here in Office 2. The lab has four main areas. Over here, on the left, is the Scenario window. This window is very important. It describes the tasks that you're required to perform during a given lab activity. Typically, the items in this bullet list provide you with all the tasks that you'll be evaluated on. You'll be expected to perform these tasks correctly as you go through the lab. If you need more space while you're working, you can hide the Scenario window by clicking this button right here, and you can click it a second time to bring it back.
The main area where you'll do most of your work is called the Workspace. It includes all the items you'll work with and configure. For example, in this simulation, we have a computer, and we have wall plates with connectors for cable internet, the network, the telephone, and for AC power.
We also have the Shelf. This holds pieces of equipment organized by category. These are the objects you'll use to complete configuration tasks over in the Workspace. You can think of the Shelf as your inventory of spare parts or an online ordering system where you can order the parts that you need.
Now, let's go through the process of completing a lab. The first thing you need to do is read the Scenario. Read it very carefully because when you're done, you're evaluated on whether you did everything it asked you to.
You'll often need to examine objects within the Workspace more thoroughly. You can use this slider to zoom in and out. You can also use the zoom out and zoom in buttons or the drop-down list here.
Before we go any further, I need to point out that each object within the Workspace occupies a certain amount of space, which is denoted by the outline that's around each object. For example, this is the area for the computer, and this is the area for the wall plates. Within each of these windows, there are buttons that allow you to change the viewing perspective for that object.
I'm currently looking at the front of the computer. But let's that suppose I need to do some work on the back. I can come up here and click the Back button. If I need to see the front of the computer again—say, to power it on—I click the Front button. You'll notice that not all of the objects have multiple views. The computer does, but the wall plates only have one view—the Front view.
Let me sort of jump ahead for the sake of showing you something. I'm going to grab the mouse and keyboard from under Input Devices on the Shelf. You're not stuck with this layout in the Workspace. For example, I could grab the mouse and move it to the other side of the keyboard or move it back.

Once you've familiarized yourself with the items in the Workspace, you need to go over here—to the Shelf—and use the categories displayed to find the objects that are required to complete the Scenario.
If you're looking at an item on the Shelf, and you're not sure what it is, click on that object's Details link. For example, I can click the Details link here for the video cable. When I do, an overview of the cable is displayed. Notice that, for this object, we see the cable itself. We can see each connector, and I can look at the front, back, and top of each one. Also, notice that when I click an item on the Shelf, it's displayed down here in the Selected Component window, and we can access the same information using the Details links down here. Being able to view the details of a particular object on the Shelf is very useful because it helps you verify that the object you've selected is the correct one for the scenario's particular requirements.
And I should point out here that, with some objects, when you view their details, you see an additional tab called Specifications, which opens a window that provides even more information. Right now, we don't have an object on the Shelf or Workspace that has a Specification tab, but some do—for example, a motherboard will most likely have one. The information there is similar to what you might find in a user manual for that particular item.
Before we can work with an object in the Workspace, we have to first add it or connect it to an item that's already there. For example, to add this Monitor to the Workspace, we expand Monitors and then drag it over here. Notice that when I do, you see yellow lines appear, which tell me where I can drop the monitor in relation to the other objects that are already there. In this case, I want to add the monitor to the Workspace right next to the PC system itself, so I'm going to drop it right here. And now, it's there. Pretty simple!
Once the object is in the Workspace, I can manipulate it to accomplish the tasks in the Scenario. In this example, I need to look at the back of the monitor, and I need to use cables to connect this monitor to the computer system and the power outlet. Let's look at the back of the computer as well as the monitor to see all the connectors.
With this done, I now need to use the appropriate cables to connect these two devices together and connect the monitor to the power outlet. Let's go over here and expand Cables, and let's connect the monitor to the computer system using a video cable. I can click on the video cable so that it appears down here, in the Selected Component window. Let's grab each connector and add it to the appropriate port on the back of the computer and monitor. And let's quickly drag this connector to the monitor.
Notice here that there are three different ports available, and as I hover over each one, it's outlined in blue. That blue rectangle tells me that this is a potential place where I could connect this particular device. It doesn't mean it's the right connector, though—it just means that it's an option you could try. In this case, I'm dealing with an HDMI connector, so I need to make sure that I drag and drop it in an HDMI port—right here. I release the mouse, and now, one end of the connector is connected to the monitor. If we look at the connector's status down here, it's got one end connected to the monitor now. The other is still unconnected. And notice that when I did that, the Partial Connections window was displayed. You'll always see this window when one end of a cable is connected, but the other end isn't.
Now we need to connect the other end of the cable to the PC system. I'm going to click and drag. And just like with the other end of the cable, I need to pick the right port to connect it to. And there it is. Once again, the status is updated down here, in the Selected Component window. One end is connected to the computer and the other to the monitor.
Now, you might be wondering, "What happens if I drop this on an incompatible connector?" Well, when you do, an error is displayed down here, saying, "Hey, you can't connect that there." Let's go ahead and put it back on the correct port. And that's one way you can connect devices together using an item from the Shelf.
There's another way to do it as well, and that's to drag the cable directly from the Shelf and then drop it on the appropriate connector. In this case, I'm going to drag the power connector, and I'm going to drop it on the monitor's power socket. Notice that this cable has two different connectors—we have a female connector and a male connector. The simulator doesn't know which end of the cable I want to connect. It brings up a list of possibilities, and I have to tell it specifically which one I want to use. Let's go ahead and use the AC Power Female Connector. And now that the end is connected to the monitor itself, let's plug the other end into the AC wall plate.
Remember, I also moved our mouse and keyboard to the Bench from the Shelf. Let's plug those in really quick. First, I'll select the keyboard, find the USB on the back of the PC, and plug it in. Now let's do the same thing for the mouse.
Before we can use the computer or monitor, we obviously need to turn them on. Let's start with the computer. If you hover over the power button, you'll notice that it's highlighted in blue. I'm going to click it to turn it on. It's telling me that the monitor has no display—that's because it's not turned on. Let's go over to the monitor and power it on as well. Now I'll click on the Windows screen.
As you can see, we have a fully simulated Windows environment, though it does function in pretty much the same way a real Windows desktop would. For example, I can click on the Start button. When I do, all of the things that you'd expect to see in the Start menu are displayed. I can search for control panel and click on it. When I do, Control Panel pops up, just like it would on a real Windows system. And using the various links in Control Panel, I can go ahead and configure this simulated workstation. For example, I could go down here to Hardware and Sound, and I could use this link right

here to add a new printer to the system. The steps that you need to take within the simulation are the same ones you'd need to take on a real Windows system.
I do need to point out that as you go through the lab exercises, you'll see that not everything in the Windows interface is enabled. If a feature isn't necessary for a lab, it's not enabled, but all the components you need to complete the Scenario will be.
Now, while the computer is up and running, we can switch back to the Workspace and view the hardware by clicking up here.
In addition to moving objects from the Shelf to the Workspace, you can do just the opposite. You can take an object that's currently in the Workspace and return it back to the Shelf. Let's grab the keyboard and move it to the shelf. When I do, I get a message that says, "Hey, I can't be moved back to the Shelf because I'm still plugged in."
Before we can put this item back, we've got to unplug it. To unplug a cable or device, simply click on it, drag the end off, and drop it somewhere within the Workspace. For example, to unplug the cable for the keyboard, I click it, drag it off, and drop it—then its status changes to unconnected. At this point, the keyboard is unplugged, so I can drop it back over here on the Shelf. And please be aware that there are some items that you can't move to the Shelf, such as the wall plate connectors.
Now, once you've completed all the tasks in the Scenario, you're ready to submit the lab for evaluation. However, I recommend that before you do this, you go back over to your Scenario and quickly review all the tasks that you were expected to complete and double-check to make sure that everything was done as required. Once you've verified that you've done everything, go up here and click Score Lab. When you do, it's going to evaluate whether or not you did everything correctly.
Notice here that we have a list of tasks that I was required to perform for the Scenario—found here, under TASK SUMMARY. Over here, I have an icon that tells me whether or not I did each one. If I didn't do a particular task, I see a red X. If I did complete a task, it's denoted with a green checkmark. Notice that, in this scenario, I didn't do everything that was required. I initially had the keyboard on the Workspace, but I took it off, so it evaluated as incorrect. And because I unplugged the cable for the keyboard, I got it wrong.
Now, this last task is actually a multi-item task, meaning that I had to complete several different sub-tasks in order to get everything correct. To see what those sub-tasks were, I click on Show Details, and it tells me that I needed to turn on the monitor and the computer. I did both, so I got those correct.
And down here, under Task Summary, is the EXPLANATION. This part of the report provides step-by-step instructions for actually completing the tasks in the Scenario. There are, of course, many ways to complete some of these tasks.
Okay, now I'm going to pause the recording while I restart the lab.
Let's go back to Office 2 Hardware. If, at any time, you're in the middle of a lab and think to yourself, "I really messed this up," you can restart the lab without scoring it. This button over here will restart the lab from the beginning without giving you a score. Be aware, though, that if you do, you'll get this message telling you that any work you've done will be lost.
That's it for this demonstration. In this demo, we learned how to use the TestOut Lab Simulator.

1.3.2 Labsim Features (Demo Video)

Transcript:

In this demonstration, we're going to spend a few minutes talking about the lab exercises in this course. You may be familiar with LabSim already, but in this course, we're introducing a few new features, so you'll want to watch this demo.

When you start a lab exercise, you'll generally see a screen like this. We have a simulated a Kali Linux environment.
Let's take a look at it. If you want to complete the lab and get everything right, you should read through this scenario very carefully. It'll usually begin by setting up the situation. It's telling you what's happened and what we're trying to do in the demo. Down here, it'll give you the specific tasks that you need to complete. For this lab, we need to crack the password on the Support computer and then crack the password on the ZIP file.
As you go through this lab exercise, you need to make sure that you complete each and every one of these requirements. When you're done with the lab, each task is evaluated, and how many you completed determines your score.
So, as you're working through the lab exercise, it's a really good idea to mentally check and say, "Okay, did I do this one?" Yes. "Did I do this one?" Yes. If you've done everything listed here according to the scenario, you'll pass the lab exercise.
Now, our new lab features in this course are questions and copy and paste.

Let's start with questions. You may be required to perform a task and look for something specific. Over here, you'll see the Answer Questions tab. I have two questions that I'll need to answer while doing this lab. It's a very good idea to open this right after you read the scenario so you know what you're looking for while you perform the steps. This particular lab wants you to enter the password for the Linux Computer and the password for the protected.zip file.
Okay, now let's move on to the copy and paste feature. Let's open a terminal, and I'll type in **ifconfig.** Now let's say, for example, that I want to copy and paste this MAC address, here. I can just highlight it like this, come down here, and right-click. When I do, it'll paste the text right here. Be aware you don't get a menu that asks you to paste; it just pastes the text when you right-click.
If there's some text over in the scenario, let's say a long password, you can also copy that and paste it somewhere else. So, as soon as I highlight the text, it's copied to the clipboard. Come over here, right-click, and it's pasted in. Let's close the terminal.
Now, within each lab, not everything is actually enabled within the simulation, only the components that you'll need to complete the scenario. So you might click on something and find that it doesn't actually work, or it might not do what you think it should do.
But we're going to look at some of the things that do work in this lab. Over here, we have our Favorite programs. The top one, here, is the Terminal. I'll open that up again. Now, be aware that many of the programs that come with Kali Linux and are launched from the terminal. For example, if the lab says to use nmap to do a scan, I can do that from here. Let's check our IP address really quick. I can do that by typing **ifconfig** and pressing Enter.Right here, I can see my IP address of 192.168.0.45. We can also type **ip addr** andpress Enter to get our IP address.
Remember we launch nmap from the terminal; let's do that now. Just type in **nmap** and press Enter.When you do that, you get a list of parameters that you can use. Right here are some examples of how to use nmap. Now let's scan our subnet. For that, type **nmap 192.168.0.0/24** and press Enter.We just did a quick default nmap scan of our subnet, and we found all these devices that are live on the subnet.
Other programs are also launched from the terminal. To launch Metasploit, we'll type **msfconsole** and press Enter, and it's launched.
Okay, let's close the terminal and look at a few of the GUI tools that are simulated. We have Ettercap here. There will be labs that require you to use Ettercap in the course. Let's close that and open up the next one, Zenmap.
Zenmap is basically a GUI version of nmap. It's used to scan networks. Let's close this and go to the next one, Wireshark.
To start a scan, we select our interface and click the shark fin up here. Let's open the terminal. I'll do an **ifconfig** to confirm my IPaddress and ping this machine, so let's type in **ping 192.168.0.46** and press Enter.
Now let's go back to Wireshark and filter by ICMP, or our ping traffic, by typing in **icmp** in the filter field.You can see we're getting all this ICMP traffic in Wireshark.
Let's go ahead and close these.
Be aware that you may be required to open multiple programs or perform tasks on multiple systems. If this is the case, the scenario will tell you. This particular scenario only requires us to work on this one system, but there will be scenarios that will ask you to work on one, two, or more different systems. You might be asking, how do I change between systems? What you need to do is come up to the overview button, right here, and click on it. When you do, the entire office environment is displayed. The current system that you're working on is highlighted. Notice, down here, that the last system I was working on was named IT-Laptop. If you need to change to a different system somewhere else in the office, locate the appropriate system in the diagram, and then just click on it. For example, I'll click on the Office1 system. Now notice I'm in a different office, working on a completely different system. Let's go the IT-Laptop system.
Since this is a simulated environment, keep in mind that keyboard shortcuts might not work as expected. So, for example, if you want to enter Ctrl+Alt+Delete, you'll be sending that command to the actual system you're on, not the simulated system. Always look for text that lets you know how to perform the alternative to shortcuts; it's typically down here, at the bottom.
Now that we've looked at some of the new features, let's complete this lab. This lab tells us to crack some passwords with John the Ripper. I'll open the terminal and, at the prompt, I'll type in **cd /usr/share/john** and press Enter.Now let's see what's in the folder. I'll type in **ls** to do that.
One of the things I want to look at is the password.lst file. This will contain a list of passwords that John the Ripper will use to try to brute force and crack the system with. You can add to this list, delete passwords, and so on. To view the contents, I'll type in **cat password.lst** and press Enter, and you can see the list is displayed. This is a short list of passwords, so be aware that normally, this will contain tens of thousands of passwords. I'll type **cd** to get back to root, here,and then **clear** to clear the screen.
To crack the password on the system, I'll type in **john /etc/shadow** and press Enter.In this course, we'll learn that with Linux, the password is actually kept in the shadow file. Right up here, we can see that our password was cracked. As

you might remember, that was one of the questions we need to answer, so let's click on Answer Questions. I'll type in my answer and minimize that box. I'll clear this screen again.
Down here, it says once you've cracked the password, you can't crack it a second time, so let's see if that's true. I'll type in **john /etc/shadow** and pressEnter, and this time, it's telling me there are no password hashes left to crack.
It also tells me that the results are located in the john.pot file, so let's look in there to view the password, just in case we forgot to answer our question. For that, I'll type in **cat ./.john/john.pot,** press Enter, and here are the results. An alternative is to type in **john /etc/shadow/** --show', and you can see the password results again.
The next step says to crack the password of the protected.zip file on the IT-Laptop. Let's say, for some reason, we don't complete this part. I'll go back up to Answer Questions, type in an answer for the second password, and click on Score Lab, down here.
My results are displayed. I got 1 out of 4 complete, or 25%. I've been in the lab for about 30 minutes. Down here, it says I didn't correctly crack the password; however, I did correctly type in the right password as an answer. I didn't even attempt this next part, and I typed in some random answer right here. And down here is the real answer.
If I'm having issues, I can come down here, read this explanation, and review the correct steps I would need to take to complete the lab.
I can scroll down and click on the Done button; the grades are recorded in the gradebook.
That's it for this demonstration. In this demo, we talked about how to complete the lab exercises in this course. We looked at the scenario. We looked at the simulated Kali Linux environment. We discussed some new features in Labsim. We talked about how to complete tasks within the environment. We talked about how to switch between systems. We also talked about some key things you need to keep in mind when you're working in the simulated environment. We ended this demonstration by discussing how the labs are scored.

2.0 Threats, Vulnerabilities, and Mitigations

2.1 Understanding Attacks

As you study this section, answer the following questions:

- What motivates threat actors to attack?
- What protections can you implement against inside threat actors?
- Which three types of threat actors are most likely to have high levels of funding?
- Why are nation-state threat actors especially dangerous?
- What attack surfaces are inherent within a supply chain?

Key terms for this section include the following:

Term	Definition
Threat actor	A person or entity responsible for an event that has been identified as a security incident or as a risk.
Internal/external	The degree of access that a threat actor possesses before initiating an attack. An external threat actor has no standing privileges, while an internal actor has been granted some access permissions.
Level of sophistication/capability	A formal classification of the resources and expertise available to a threat actor.
Resources/funding	The ability of threat actors to draw upon funding to acquire personnel, tools, and development of novel attack types.
Service disruption	A type of attack that compromises the availability of an asset or business process.
Data exfiltration	The process by which an attacker copies data from a private network to an external network.
Disinformation	A type of attack that falsifies an information resource that is normally trusted by others.
Blackmail	Demanding payment to prevent the release of information.
Extortion	Demanding payment to prevent or halt some type of attack.

Fraud	Falsifying records, such as an internal fraud that involves tampering with accounts.
Hacker	Often used to refer to someone who breaks into computer systems or spreads viruses. Ethical hackers prefer to think of themselves as experts on and explorers of computer security systems.
Unauthorized hacker	A hacker operating with malicious intent.
Authorized hacker	A hacker engaged in authorized penetration testing or other security consultancy.
Unskilled attacker	An inexperienced attacker that typically uses tools or scripts created by others.
Hacktivist	A threat actor that is motivated by a social issue or political cause.
Advanced persistent threat (APT)	An attacker's ability to obtain, maintain, and diversify access to network systems using exploits and malware.
Nation-state actors	A type of threat actor that is supported by the resources of its host country's military and security services.
Organized crime	A type of threat actor that uses hacking and computer fraud for commercial gain.
Internal threat	A type of threat actor who is assigned privileges on the system that cause an intentional or unintentional incident.
Unintentional or inadvertent insider threat	A threat actor that causes a vulnerability or exposes an attack vector without malicious intent.
Shadow IT	Computer hardware, software, or services used on a private network without authorization from the system owner.
Vulnerable software	Weakness that could be triggered accidentally or exploited intentionally to cause a security breach.
Unsupported systems	Product life cycle phase where mainstream vendor support is no longer available.
Unsecure network	Configuration that exposes a large attack surface, such as through unnecessary open service ports, weak or no authentication, use of default credentials, or lack of secure communications/encryption.

Lure	An attack type that will entice a victim into using or opening a removable device, document, image, or program that conceals malware.
Supply chain	The end-to-end process of supplying, manufacturing, distributing, and finally releasing goods and services to a customer.

This section helps you prepare for the following certification exam objectives:

Exam	Objective

CompTIA Security+ SY0-701	2.1 Compare and contrast common threat actors and motivations.
	• Threat actors
	  ○ Nation-state
	  ○ Unskilled attacker
	  ○ Hacktivist
	  ○ Insider threat
	  ○ Organized crime
	  ○ Shadow IT
	• Attributes of actors
	  ○ Internal/external
	  ○ Resources/funding
	  ○ Level of sophistication/capability
	• Motivations
	  ○ Data exfiltration
	  ○ Espionage
	  ○ Service disruption
	  ○ Blackmail
	  ○ Financial gain
	  ○ Philosophical/political beliefs
	  ○ Ethical
	  ○ Revenge
	  ○ Disruption/chaos
	  ○ War
	
	2.2 Explain common threat vectors and attack surfaces.
	• Message-based
	  ○ Email
	  ○ Short Message Service (SMS)
	  ○ Instant messaging (IM)
	• Image-based
	  ○ File-based
	  ○ Removable device
	  ○ Vulnerable software
	  ▪ Client-based vs. agentless
	  ○ Unsupported systems and applications
	  ○ Unsecure networks
	  ▪ Wireless
	  ▪ Wired

	▪ Bluetooth ○ Open service ports ○ Default credentials ○ Supply chain ▪ Managed service providers (MSPs) ▪ Vendors ▪ Suppliers 2.3 Explain various types of vulnerabilities. • Supply chain ○ Service provider ○ Hardware provider ○ Software provider 2.4 Given a scenario, analyze indicators of malicious activity. • Application attacks ○ Privilege escalation 2.5 Explain the purpose of mitigation techniques used to secure the enterprise. • Least privilege

2.1.1 Threat Actor Types (Lesson Video)

Transcript:

In cybersecurity, a threat actor is any individual or entity that carries out an attack. There are different types, attributes, and motivations of which to be aware. For example, a hacker trying to exploit a vulnerability has a different attack profile than

an organized crime group waging an assault on your network.
Before we look at the threat actors, it's important to understand their motivation. Let's look at the difference between opportunistic and targeted attacks. In an opportunistic attack, the threat actor usually tries to make easy money as fast as possible and with minimal effort. Because hiding their tracks and presence is time-consuming, they usually won't bother. They want to get in, grab the goods, and get out. Think of it as the smash-and-grab of cyberattacks.
Opportunistic attacks are unstructured and scan a wide range of systems for known vulnerabilities, such as old software, exposed ports, default configurations, etc. A common example of an opportunistic attack is ransomware.
A targeted attack, on the other hand, is much more dangerous and difficult to defeat. A targeted attack is structured and focused on a specific organization or person. The motivation for a targeted attack is data exfiltration. The data is often used for other purposes, such as espionage, blackmail, financial gain, or revenge.
Now, let's look at different threat actors. An insider threat is anyone who has received rights or privileges to access systems as part of their responsibilities to the organization. This can be employees, contractors, or even guests who may access the network temporarily. If the organization doesn't have good offboarding controls, there's the blurred case of former insiders, such as ex-employees now working at another company or dismissed and now harbor a grievance.
The main motivators for a malicious internal threat actor are revenge and financial gain. You must also assess the possibility that an insider threat may be working in collaboration with an external threat actor or group. A whistleblower is someone with an ethical motivation for releasing confidential information. While this could be classed as an internal threat in some respects, it's important to realize that whistleblowers can't themselves be threatened or labeled in any way that seems retaliatory or punitive.

Becoming an internal threat actor (insider) doesn't always require an employee to make a conscious decision to carry out an attack. Insider threats can also arise from unintentional sources. An unintentional or inadvertent insider threat is often caused by a lack of awareness or carelessness, such as users demonstrating poor password management. Without proper training, they'll continue to compromise the organization in ignorance.

Another example of an unintentional insider threat is the concept of shadow IT. Shadow IT refers to hardware or software purchased or introduced to the workplace without the sanction of the IT department and without going through a procurement and security analysis process.

Many employees want quick solutions and may download or use apps and services that aren't IT-approved. The problem of shadow IT is exacerbated by the proliferation of cloud services and mobile devices, which are easy for users to obtain. Shadow IT creates a new unmonitored attack surface for malicious adversaries to exploit.

Unless the IT department has approved the solution, they could pose a threat to security. The key takeaway is that insiders have easier access to company assets than an outsider trying to break in, making them a more dangerous threat.

External threat actors are commonly referred to as hackers. The term hacker describes an individual with the skills to gain access to computer systems through unauthorized or unapproved means. Originally, hacker was a neutral term for a user who excelled at computer programming and computer system administration. However, the term gradually became associated with illegal or malicious system intrusions. The terms unauthorized (previously known as black hat) and authorized (previously known as white hat) are used to distinguish these motivations. It's also helpful to define additional threat actors based on different motivations and capabilities.

An unskilled attacker is someone who uses hacker tools without necessarily understanding how they work or having the ability to craft new attacks. Unskilled attacks might have no specific target or any reasonable goal other than gaining attention or proving technical abilities. Today, many threat actors are now likely to work as part of a team or group. The collaborative team effort means that these threat actors are able to develop sophisticated tools and novel strategies.

A hacktivist group, such as Anonymous, WikiLeaks, or LulzSec, uses cyber weapons to promote a political agenda. Hacktivists might attempt to use data exfiltration to obtain and release confidential information to the public domain, perform service disruption attacks, or deface websites to spread disinformation. Political, media, and financial groups and companies are most at risk of becoming a target for hacktivists, but environmental and animal advocacy groups may target companies in a wide range of industries.

In many countries, cybercrime has overtaken physical crime in terms of the number of incidents and losses. Organized crime can operate across the internet from a different jurisdiction than its victim, increasing the complexity of prosecution. Criminals will seek any opportunity for profit, but typical activities are financial fraud—against individuals and companies—and blackmail/extortion.

Most espionage is thought to be pursued by state actors, but it's not inconceivable that a business competitor might use cyber espionage against its competitors. Such attacks could aim at theft, disrupt a competitor's business, or damage their reputation. Competitor attacks might be facilitated by employees who have recently changed companies and bring insider knowledge with them.

Most nation-states have developed cybersecurity expertise and will use cyber weapons to achieve military and commercial goals. Nation-state actors have been implicated in many attacks, particularly on energy, health, and electoral systems. The goals of state actors are primarily disinformation and espionage for political or military strategic advantages, but it's known for countries to target companies for financial gain.

The term advanced persistent threat (APT) was coined to understand the behavior underpinning modern types of cyber adversaries. Rather than think in terms of systems being infected with a virus or Trojan, an APT refers to the ability of an adversary to achieve an ongoing compromise of network security—to obtain and maintain access—using various tools and techniques.

Well, that's it for this lesson. In this lesson, we discussed different types of attacks, such as opportunistic and targeted attacks. We also talked about different threat actors, including insiders, hackers, organized crime, competitors, and nation-states.

2.1.2 Threat Actor Types Facts

Historically, cybersecurity techniques relied on the identification of static known threats, such as viruses or rootkits, Trojans, botnets, and exploits for specific software vulnerabilities. It is relatively straightforward to identify and scan for these types of threats with automated software. Unfortunately, adversaries were able to develop means of circumventing this type of signature-based scanning.

The sophisticated nature of modern cybersecurity threats requires the creation of profiles of threat actor types and behaviors. This analysis involves identifying the attributes of threat actors' location, capability, resources/funding, and motivation. To evaluate these factors, you must be able to evaluate the sources of threats or threat actors. This topic will help you to classify and evaluate the motivation and capabilities of threat actor types so that you can assess and mitigate risks more effectively.

This lesson covers the following topics:

- Attributes of threat actors
- Motivations of threat actors
- Types of threat actors

Attributes of Threat Actors

Attribute	Description
Internal/external	Internal/external refers to the degree of access a threat actor possesses before initiating an attack. An external threat actor has no account or authorized access to the target system. A malicious external threat must infiltrate the security system using unauthorized access, such as breaking into a building or hacking into a network. Note that an external actor may perpetrate an attack remotely or on-premises. It is the threat actor that is external rather than the attack method. Conversely, an internal/insider threat actor has been granted permissions on the system. This typically means an employee, but insider threats can also arise from contractors and business partners.
Sophistication/capability	The level of sophistication/capability refers to a threat actor's ability to use advanced exploit techniques and tools. The least capable threat actor relies on commodity attack tools that are widely available. More capable actors can fashion new exploits in operating systems, applications software, and embedded control systems. At the highest level, a threat actor might use non-cyber tools such as political or military assets.
Resources/funding	A high level of capability must be supported by resources/funding . Sophisticated threat actor groups need to be able to acquire resources, such as customized attack tools and skilled strategists, designers, coders, hackers, and social engineers. The most capable threat actor groups receive funding from nation-states and organized crime.

Motivations of Threat Actors

Motivation is the threat actor's reason for perpetrating the attack. A malicious threat actor could be motivated by greed, curiosity, or some grievance, for instance. Threats can be characterized as structured/targeted or unstructured/opportunistic, depending on how widely an attack is perpetrated. For example, a criminal gang attempting to steal customers' financial data from a company's database system is a structured, targeted threat. An unskilled hacker launching some variant of the "I Love You" email worm sent to a stolen mailing list is an unstructured, opportunistic threat.

A threat actor with malicious motivation can be contrasted with an accidental or unintentional threat actor. An unintentional threat actor represents accidents, oversights, and other mistakes. To help analyze motivations, it is first useful to consider the general strategies that a threat actor could use to achieve an objective:

- **Service disruption** — prevents an organization from working as it does normally. This could involve an attack on their website or using malware to block access to servers and employee workstations. Service disruption can be an end in itself if the threat actor's motivation is to sow chaos or gain revenge. Service

disruption can be used as a blackmail threat, or it can be used as a tactic in the pursuit of some different strategic objective.

- **Data exfiltration** — transfers a copy of some type of valuable information from a computer or network without authorization. A threat actor might perform this type of theft because they want the data asset for themselves, so they can exploit its loss as blackmail or sell it to a third party.
- **Disinformation** — falsifies some type of trusted resource, such as changing the content of a website, manipulating search engines to inject fake sites, or using bots to post false information to social media sites.

You can relate these strategies to how they affect the CIA triad: data exfiltration compromises confidentiality, disinformation attacks integrity, and service disruption targets availability.

Chaotic Motivations

In the early days of the internet, many service disruptions and disinformation attacks were perpetrated with the simple goal of causing chaos. Hackers might deface websites or release worms that brought corporate networks to a standstill for no other reason than to gain credit for the hack.

This type of vandalism, for its own sake, is less prevalent now. Attackers might use service disruption and disinformation to further political ends, or nation-states might use it to further war aims. Another risk is threat actors motivated by revenge. Revenge attacks might be perpetrated by an employee, former employee, or any external party with a grievance.

Financial Motivations

As hacking and malware became more sophisticated and better commodified, the opportunities to use them for financial gain grew quickly. If an attacker is able to steal data, they might be able to sell it to other parties. Alternatively, they might use an attack to threaten the victim with blackmail or extortion or to perpetrate fraud:

- Blackmail is demanding payment to prevent the release of information. A threat actor might have stolen information or created false data that makes it appear as though the target has committed a crime.
- Extortion is demanding payment to prevent or halt some type of attack. For example, a threat actor might have used malware to block access to an organization's computers and demand payment to unlock them.
- Fraud is falsifying records. Internal fraud might involve tampering with accounts to embezzle funds or inventing customer details to launder money. Criminals might use disinformation to commit fraud, such as posting fake news to affect the share price of a company, promoting pyramid schemes, or creating fake companies.

Political Motivations

A political motivation means that the threat actor uses an attack to bring about some type of change in society or governance. This can cover a very wide range of motivations:

- An employee acting as a whistleblower because of some ethical concern about the organization's behavior.
- A campaign group disrupting the services of an organization that they believe acts in contradiction to their ethical or philosophical beliefs.
- A nation-state using service disruption, data exfiltration, or disinformation against government organizations or companies in another state in pursuit of war aims.

Nation-states commonly perpetrate espionage and disinformation attacks against one another, whether or not they are at war. In cybersecurity, espionage is a type of data exfiltration aimed at learning secrets rather than selling them or using the theft for blackmail.

There is also the threat of commercial espionage, where a company attempts to steal the secrets of a competitor.

Types of Threat Actors

It can also be helpful to evaluate the risk that well-known threat actor types or profiles pose to a business, given awareness of the general strategies and motivations. Note that the detailed process of analyzing the threat posed by a particular actor or adversary group is described as threat modeling.

Hackers

Hacker describes an individual with the skills to gain access to computer systems through unauthorized or unapproved means. Originally, *hacker* was a neutral term for a user who excelled at computer programming and computer system administration. Hacking into a system was a sign of technical skill and creativity that gradually became associated with illegal or malicious system intrusions. The terms unauthorized (previously known as black hat) and authorized (previously known as white hat) are used to distinguish these motivations. An authorized hacker always seeks authorization to perform penetration testing of private and proprietary systems.

Unskilled Attackers

An unskilled attacker is someone who uses hacker tools without necessarily understanding how they work or having the ability to craft new attacks. Unskilled attacks might have no specific target or any reasonable goal other than gaining attention or proving technical abilities.

Hacker Teams and Hacktivists

The historical image of a hacker is that of a loner, acting as an individual with few resources or funding. While the "lone hacker" remains a threat that must be accounted for, threat actors are now likely to work as part of a team or group. The collaborative team effort means that these threat actors are able to develop sophisticated tools and novel strategies.

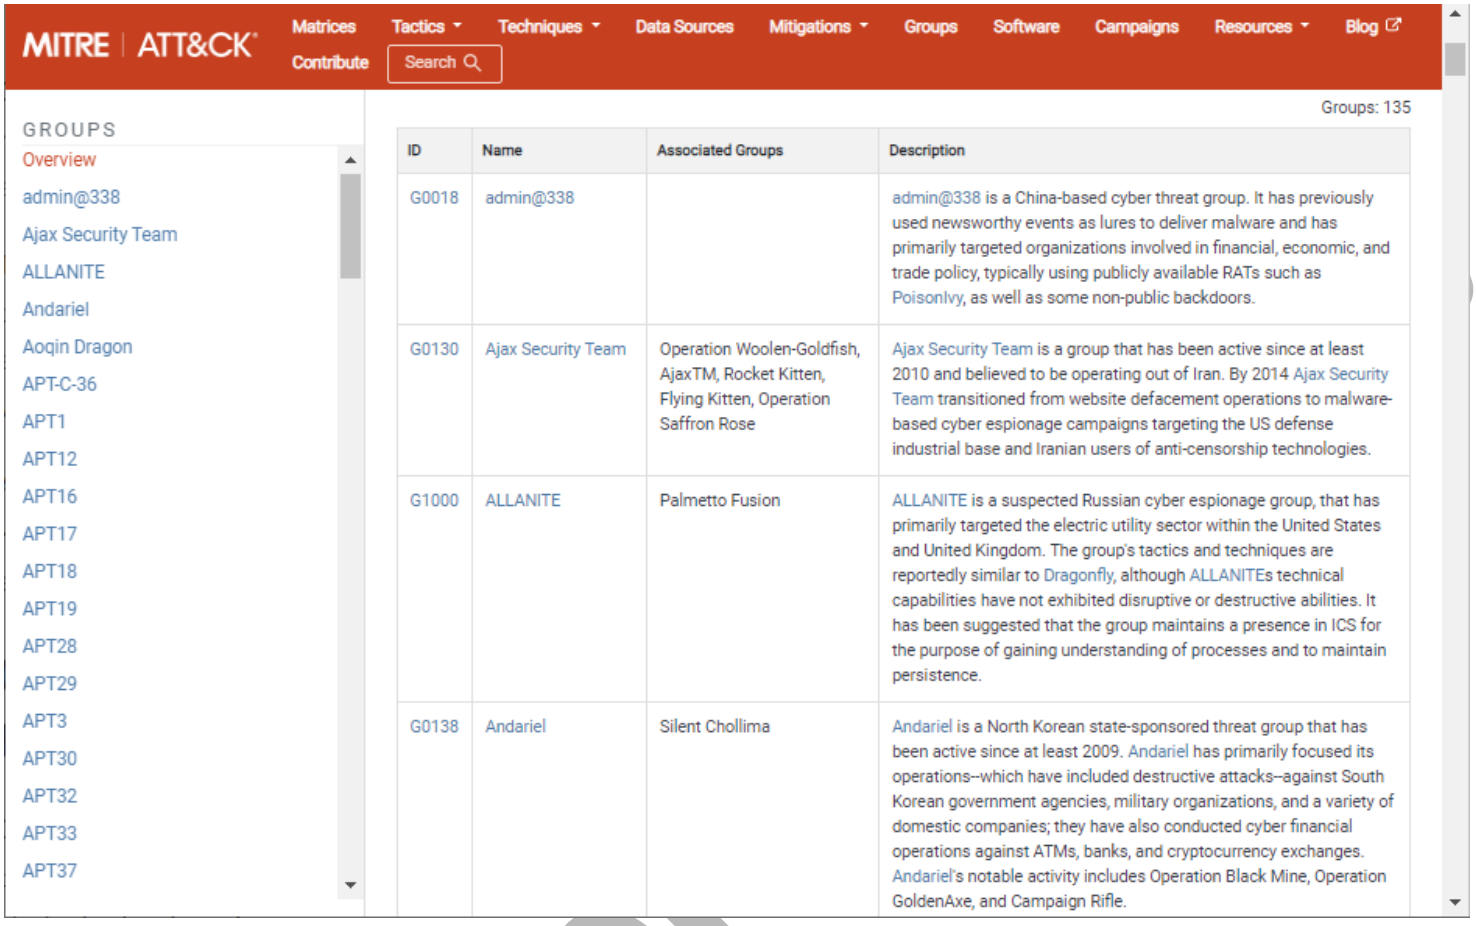
A *hacktivist group* , such as Anonymous, WikiLeaks, or LulzSec, uses cyber weapons to promote a political agenda. Hacktivists might attempt to use data exfiltration to obtain and release confidential information to the public domain, perform service disruption attacks, or deface websites to spread disinformation. Political, media, and financial groups and companies are most at risk of becoming a target for hacktivists. Still, environmental and animal advocacy groups may target companies in a wide range of industries.

Nation-State Actors

Most nation-states have developed cybersecurity expertise and will use cyber weapons to achieve military and commercial goals. The security company Mandiant's APT1 report into Chinese cyber espionage units, shaped the language and understanding of cyber-attack lifecycles.

The term advanced persistent threat (APT) was coined to understand the behavior underpinning modern types of cyber adversaries. Rather than think in terms of systems being infected with a virus or Trojan, an APT refers to the ability of an adversary to achieve an ongoing compromise of network security—to obtain and maintain access—using various tools and techniques.

Nation-state actors have been implicated in many attacks, particularly on energy, health, and electoral systems. The goals of state actors are primarily disinformation and espionage for strategic advantage. Still, it is known for countries—North Korea is a good example—to target companies for financial gain.



Researchers such as The MITRE Corporation report on the activities of organized crime and nation-state actors. (Screenshot © 2023 The MITRE Corporation. This work is reproduced and distributed with the permission of The MITRE Corporation.)

State actors will work at arm's length from the national government, military, or security service that sponsors and protects them, maintaining "plausible deniability." They are likely to pose as independent groups or even as hacktivists. They may wage false flag disinformation campaigns that try to implicate other states.

Organized Crime and Competitors

In many countries, cybercrime has overtaken physical crime in terms of the number of incidents and losses. Organized crime can operate across the internet from a different jurisdiction than its victim, increasing the complexity of prosecution. Criminals will seek any opportunity for profit, but typical activities are financial fraud—against individuals and companies—and blackmail/extortion.

Most espionage is thought to be pursued by state actors, but it is not inconceivable that a rogue business might use cyber espionage against its competitors. Such attacks could aim at theft, disrupt a competitor's business, or damage their reputation. Competitor attacks might be facilitated by employees who have recently changed companies and bring insider knowledge with them.

Internal Threat Actors

Many threat actors operate externally from the networks they target. An external actor has to break into the system without having any legitimate permissions. An internal threat (or insider threat) arises from an actor identified by the organization and

granted some type of access. Within this group of internal threats, you can distinguish insiders with permanent privileges, such as employees, from insiders with temporary privileges, such as contractors and guests.

There is the blurred case of former insiders, such as ex-employees now working at another company or who have been dismissed and now harbor a grievance. These can be classified as internal threats or treated as external threats with insider knowledge and possibly some residual permissions if effective offboarding controls are not in place.

The main motivators for a malicious internal threat actor are revenge and financial gain. Like external threats, insider threats can be opportunistic or targeted. An employee who plans and executes a campaign to modify invoices and divert funds is launching a structured attack. An employee who tries to guess the password on the salary database a couple of times, having noticed that the file is available on the network, is perpetrating an opportunistic attack. You must also assess the possibility that an insider threat may be working in collaboration with an external threat actor or group.

A whistleblower is someone with an ethical motivation for releasing confidential information. While this could be classed as an internal threat in some respects, it is important to realize that whistleblowers making protected disclosures—such as reporting financial fraud through an authorized channel—cannot themselves be threatened or labeled in any way that seems retaliatory or punitive.

Insider threats can also arise from unintentional sources. Unintentional or inadvertent insider threat is often caused by a lack of awareness or carelessness, such as users demonstrating poor password management. Another example of unintentional insider threat is the concept of shadow IT , where users purchase or introduce computer hardware or software to the workplace without the sanction of the IT department and without going through a procurement and security analysis process. The problem of shadow IT is exacerbated by the proliferation of cloud services and mobile devices, which are easy for users to obtain. Shadow IT creates a new unmonitored attack surface for malicious adversaries to exploit.

2.1.3 General Attack Strategy (Lesson Video)

Transcript:

Let's talk about the general attack strategy threat agents use to conduct an exploit.

Although there are a multitude of ways to carry out an exploit, many threat agents will actually follow the same general attack strategy. Understanding the methodology behind common attacks can help you defend your information assets better.
The first step in most attacks is some type of reconnaissance. The attacker needs to probe the target computer system or target network for vulnerabilities. They're also trying to gather information. They want to know about system hardware and network configurations. They want to know about individual users and their susceptibility. They'll use different tools to find different information.
An agent conducting a social engineering attack needs to gather information about the users on the system. They might dumpster dive, sifting through garbage to try to find critical information, such as passwords that have been written down. Any information about network users, systems, and processes can be useful to an attacker.
Another tactic is to call individual users and intimidate them enough to give out important information. An attacker will try to sound like someone who has authority in the organization. They'll threaten employees with discipline to acquire sensitive information.
An alternative to the intimidation approach is the sympathetic approach. The attacker will pretend to be a fellow employee at the organization who is in a desperate situation that can only be rectified by certain information.
There are variations on these methodologies, of course. For example, it is possible for someone to use aggressive emails, texts, or messages on social media to gain information.
If an agent is conducting a technical exploit, then the tools used will be a little bit different. A very common tactic is to use the port scan with the utility. The nmap utility is a security scanner that hackers use a lot. It scans a system to find out what ports are open. An open port on a system represents a potential hole that can be exploited.
A ping sweep is another favorite attack tool. The attacking system sends a ping, or an ICMP echo request, to a range of IP addresses say 192.168.1.1 to 192.168.1.254. Any valid IP address configured to respond to ping requests will

respond with an ICMP echo reply packet. This tells an attacker which IP addresses are active and available on the network.
If the reconnaissance goes well and the attacker has a lot of information to work with, the next step is breaching the system.
The way the breach is conducted depends on the type of exploit involved. If it's a social engineering exploit, they're going to use the data gathered from the user, such as their username and password. Alternatively, they could get a user to do something for them.
If the exploit is a technical exploit, then different processes will be used. The attacker might try to cause an exception error with a buffer overflow that gives them access to the system. They might identify an open port on a network server and try to exploit it. They might try to use password-cracking software to crack a password.
Once the system has been breached, the next step is to escalate privileges. Most breaches provide the attacker with a limited amount of access to the system, since most user accounts don't have high-level privileges. Even if they used a technical exploit, an attacker will probably only have a low level of access. That's not good enough. They want escalated privileges to the system that they're attacking. There are a variety of ways to do this, but many involve exploiting weaknesses in the system's design.
In addition to escalating privileges, attackers will also want to create an easy way to access the system a second time. This is called a backdoor. It makes it so they won't have to go through the reconnaissance and breaching process the next time they want to get in. There are all kinds of ways to set up a backdoor.
For example, an attacker could set up their own user account. They may even create a user account that looks the same as a user account that already exists. Through social engineering, they may have identified the user name of a particular person in the organization. And with some operating systems, you can create a username and then put a space at the end of it. The operating system will recognize it as a completely different user account, but most administrators will see it as identical to the legitimate user account.
The next phase in the attack is the stage. This step is optional; if the exploit was designed to steal information like credit card numbers, then an attacker is not going to be concerned with spreading the attack to other systems. If, however, the attack is an internet worm that's going to be spread all over the world, then the attacker wants to use the system that they've breached to spread the attack. In other words, the breached system becomes a staging ground for mounting attacks on additional systems.
The last step is to actually exploit. The attacker tries to gain whatever they initially attacked the system for. It could be customer information, ID numbers, credit card numbers, or embarrassing personal information. The goal of the exploit may not even be to steal; it might seek to create so much traffic on a particular system that the system can no longer function normally and provide services. In this way, the attack is actually denying services, rather than stealing anything. An exploit could also seek to corrupt or modify information. Of course, the actual exploit conducted depends on the motivation of the threat agent. An attacker could be trying to steal information for financial gain or trying to get back at an organization for a perceived wrong. They might be a cyber terrorist trying to bring down a critical infrastructure system.
Understanding general attack strategies will help you, as a security administrator, to better identify when attacks are occurring and defend your system against them. It can also help you identify weak spots in your system so you can prevent attacks altogether.
To quickly review, the steps in a general attack strategy are reconnaissance, breaching, escalating privileges, staging, and exploiting.

2.1.4 General Defense Strategy (Lesson Video)

Transcript:

As a security administrator, you're responsible for protecting your information from an almost limitless number of attacks and exploits. To guard your information from attacks, you need to formulate a general defense strategy using several fundamental security principles.

The first principle we need to look at is layering. Your defenses need to be layered. This means using multiple strategies to protect information.
For example, in order to log in to a computer system, by default, all you have to provide is the user name and password. Well, that's good--but what if the user name and password get compromised? The attacker who obtained the user name and password now has access to whatever privileges that user account has within the system.

But what if you required a fingerprint that's read via a biometric scanner in addition to a user name and password? With this extra security precaution, we create a layered defense for that particular system. Someone could come along and compromise a particular user's user name and password on that system, but they still can't log in because they don't have that user's fingerprint.

The one thing you need to remember when you're dealing with most attackers is that they're looking for low-hanging fruit; in other words, they're lazy. Let's say you have a choice of three different systems to try to compromise, and they're all worth about the same. Two of them are extremely difficult, with layered defenses that will take a lot of work and risk to compromise. The third system is really lax on their security.

Which one are you going to attack? The third one! So, by using layered defenses, you make sure that your system or network is not a target of opportunity. Is that going to deter a determined attacker, like a disgruntled employee or a cyber terrorist? No. To them, you're still a target of opportunity because they're not focused on anybody else--they are focused on you. But using layered defenses still makes it more difficult to access your system.

The next part of your overall defensive strategy is minimizing user access. You need to protect your information from the inside and the outside. Basically, each user should have access to the information they need to do their job and no more. This is called the principle of least privilege. One problem with the principle of least privilege is that some operating systems give users access to only what they have been specifically granted privileges to, while other operating systems basically give everybody access to everything unless they are specifically denied access. What you need to do is look at the systems where the information you're protecting is stored and determine whether the operating system is the first type or the second type.

Here's an example: We have three users who use this particular server. It's a Linux server. We have Fred, Mary, and Bob. Fred needs access to his home directory on the server, which is located in the /Home/Fred directory. Therefore, according to the principle of least privilege, Fred should have access to only this directory on that server, and no others. Mary needs to have access to her home directory right here, /Home/Mary. She is also working on a project that's developing a new widget for the company. She needs access a special directory named Widgets, too. Additionally, she's been granted access to a shared area right here on the server hard drive, where multiple users can share their information. So she is given that level of access. Bob, over here, has access to his home directory, /Home/Bob, and he has also been granted access to the shared directory /Shared.

This is a very common setup in the real world, but there's a problem with it: Individual users have home directories that are protected and inaccessible to anybody else. But then the administrator sets up shared directories, and it becomes much easier for the principle of least privilege to be violated. The problem isn't with the directory itself; the problem is with what people do with that shared directory. From a productivity standpoint, shared directories work well because they allow multiple people to collaborate on documents and work together efficiently. A user can put a file into the shared folder, and anyone who has access to the shared folder can open the file and do whatever work they need to.

A problem that can occur with shared directories, however, is users adding sensitive files to the shared folder. It can happen that users that have access to the shared folder should not have access to certain files that have been added to the shared folder. Shared folders ruin the strict privilege denial system.

The next component that you need to include in your overall defensive posture is randomness. The problem here is that human beings tend to be creatures of habit. We establish predictable patterns of behavior. For example, you probably take the same route to work at the same time each day. Once you're at work you probably follow the same daily routine checking emails, attending meetings, writing reports, completing tasks and the same weekly routine. This is bad from an information security standpoint because attackers can identify these personal patterns and then use them to their advantage.

As the security administrator for a system, you need to randomize your personal habits as part of your defensive strategy. If someone wants to break into your system and they're using a social exploit combined with a technical exploit, they might observe what time you come to work, what time you go on break, what time you run backups, etc. Whatever information they can glean during the reconnaissance phase of an attack helps them determine where vulnerabilities lie.

Another good thing to do is to randomize password change intervals. Security administrators usually make it so that every user has to change their password after 90 days. Well, what does that tell an attacker? They know that if they manage to compromise a user name and password, they've got a certain amount of days while that password is still valid. But if you set up your password change intervals to be 90 days once, then 30 days the next time, then 60 days, then 15 days, etc., then the attacker does not know how long that password is good for.

You should also try to obscure information. In other words, you want to make the reconnaissance process as unreliable and unpredictable as possible. You don't want an attacker to deduce behavioral trends and gather information about your system. One common recon tactic is to use ping sweeps. One thing you can do to obscure information is to make it so ping sweeps don't work. You do this by configuring a host-based firewall on every system and configuring that firewall not to respond to ICMP Echo requests. Basically, you make the systems un-pingable. If you disable ICMP Echo requests

in the host-based firewall, they won't respond. You obscure how many systems are in your network, as well as which IP addresses are assigned.

The last principle of a defensive posture is to keep things simple. Many administrators want to implement all the latest and most complex security measures to protect their information. That's good, but it becomes a problem if defenses are so complex that they become unusable. It is better to keep a simple defensive mechanism. Here, simple means easy to understand. If you don't fully understand how to manage a type of defense, don't use it until you are well-trained in how it works. You can't make sure a security system is doing its job if you don't know what it's supposed to do. You need to know how to interpret the output from the system and how to fix problems when they occur.

As a security administrator, you need to implement the concepts that we talked about in your defensive strategy in order to create a system that's much more difficult to breach or exploit.

In this lesson, we covered the various components that comprise an overall defensive strategy. We talked about layered defenses, the principle of least privilege, varied defense mechanisms, randomizing behaviors, and keeping things simple.

2.1.5 Attack and Defense Strategy Overview

Understanding the methodology behind common attacks can help you better defend your assets.

This lesson covers the following topics:

- Attack strategies
- Defense methodologies

Attack Strategies

General attack strategies incorporate some or all of the techniques explained in the following table.

Strategy	Description
Perform reconnaissance	*Reconnaissance* is the process of gathering information about an organization, including: • System hardware information • Network configuration • Individual user information
Use social engineering	*Social engineering* is the process of manipulating others into providing sensitive information. Social engineering tactics include: • Intimidation • Sympathy
Use technical approaches	A *technical* approach to obtaining information includes using software or utilities to find vulnerabilities in a system. Methods often used by hackers are: • Port scan • Ping sweep
Breach the system	A *breach* is the penetration of system defenses. It is often achieved by using information gathered through reconnaissance.

Strategy	Description
Escalate privileges	*Escalating privileges* is a primary objective of an attacker. Once an attacker has breached the system, obtaining higher privileges allows the attacker to access more information and gain greater control within the system.
Create a backdoor	*Creating a backdoor* is an alternative method of accessing an application or operating system for troubleshooting. Hackers often create backdoors to exploit a system without being detected.
Stage computers	*Staging* a computer involves preparing it to perform additional tasks in the attack, such as installing software designed to attack other systems. This is an optional step.
Exploit vulnerabilities	An *exploitation* takes advantage of known vulnerabilities in software and systems. Once a vulnerability has been exploited, an attacker can often: • Steal information • Deny services • Crash systems • Modify/alter information

Defense methodologies

General defense methodologies include the following items:

Methodology	Description
Layering	*Layering* involves implementing multiple security strategies to protect the same asset. *Defense in depth* or *security in depth* is based on the premise that no single layer is completely effective in securing assets. The most secure system/network has many layers of security and eliminates single points of failure.
Principle of least privilege	The *principle of least privilege* states that users or groups are given only the access they need to do their jobs and nothing more. When assigning privileges, be aware that it is often easier to give a user more access when it is needed than to take away privileges that have already been granted.
Variety	Defensive layers should incorporate a variety of methods. Implementing multiple layers of the same defense does not provide adequate protection against attacks.
Randomness	*Randomness* in security is the constant change in personal habits and passwords to prevent predictable behavior.
Simplicity	Security measures should provide protection but not be so complex that it is difficult to understand and use.

2.1.6 Attack Surfaces (Lesson Video)

Transcript:

The attack surface is all the points at which a malicious threat actor could try to exploit a vulnerability. To evaluate the attack surface, you need to consider the attributes of threat actors that pose the most risk to your organization.

From a threat actor's perspective, each part of the attack surface represents a potential vector for attempting an intrusion. A threat vector is the path that an attacker uses to execute a data exfiltration, service disruption, or disinformation attack. Sophisticated threat actors will make use of multiple vectors. In this lesson, we'll look at several of those vectors.

Vulnerable software contains a flaw in its code or design that can be exploited to circumvent access control or to crash the process. Typically, vulnerabilities can only be exploited in specific circumstances and are often patched by the vendor. However, because of the complexity of modern software and the speed with which new versions must be released to market, almost no software is free from vulnerabilities. Organizations that might not have an effective patch management system are exposed to this commonly exploited threat vector.

Vulnerable software continues to be an effective threat vector due to the continued use of unsupported systems and applications. An unsupported system is one where its vendor no longer develops updates and patches. Unless the organization is able to patch the faulty code itself, these services and apps will be highly vulnerable to exploits. One of the best ways to mitigate this risk is to isolate these systems.

Scanning software helps organizations automate the discovery and classification of software vulnerabilities. This scanning software can be implemented as a client-based agent, where the agent runs as a scanning process installed on each host and reports to a management server. Alternatively, the vulnerability management product might use agentless techniques to scan a host without requiring any sort of installation.

To execute malicious code on a system, a threat actor must be able to run exploit code on the system or over a network. Let's look at some specific threat vectors that can expose unsecured networks.

Direct Access — when the threat actor uses physical access to the site or system to perpetrate an attack.

Wired Network — when a threat actor with access to the site attaches an unauthorized device to a physical network port, and the device is permitted to communicate with other hosts.

Remote and Wireless Network—when the attacker obtains credentials for a remote access or wireless connection to the network or cracks the security protocols used for authentication.

Cloud Access—many companies now run part or all of their network services via internet-accessible clouds. The attacker only needs to find one account, service, or host with weak credentials to gain access.

Some additional network vectors include the following:

Bluetooth Network—a threat actor can exploit a vulnerability or misconfiguration to transmit a malicious file to a user's device over the Bluetooth personal area wireless networking protocol.

Default Credentials—the attacker gains control of a network device or app because it has been left configured with a default password. Default credentials are likely to be published in the product's setup documentation or are otherwise easy to discover.

Open Service Port—the threat actor is able to establish an unauthenticated connection to a logical TCP or UDP network port. The server will run an application to process network traffic arriving over the port. The software might be vulnerable to exploit code or to service disruption.

A lure is something superficially attractive or interesting that causes its target to want it, even though it may be concealing something dangerous, like a hook. In cybersecurity terms, when the target opens the file bait, it delivers a malicious payload hook that'll typically give the threat actor control over the system or perform service disruption.

A common lure attack involves removable devices. An attacker conceals malware on a USB thumb drive or memory card and tries to trick employees into connecting the media to a device. In a drop attack, the threat actor simply leaves infected USB sticks near offices with the expectation that at least one employee will pick one up and plug it into a computer. They can contain executable files concealing malware, word processing documents or PDF files with embedded malicious code, or image files with exploit code concealed in the image.

File-based lures need a mechanism to deliver the file and a message that'll trick a user into opening the file on their computer. Consequently, any features that allow direct messaging to users must be considered as part of the potential attack surface. Message-based threats involve malicious activities carried out through different communication channels, such as email, short message services (SMS), and instant messaging.

A common vector involves sending email messages with malicious file attachments or fake URLs, commonly referred to as phishing. The attacker also uses social engineering techniques to persuade or trick the user into opening the attachment or clicking on the URL.

Another vector utilizes the Short Message Service (SMS) to send a file or a link to a mobile device using the text messaging handler built into smartphone firmware. This practice is called smishing, and it's difficult to monitor because it's operated by the handset or subscriber identity module (SIM) card provider.

Attackers can also exploit instant messaging (IM) platforms to deliver malicious links, files, or messages, attempting to compromise devices or steal sensitive data.
Web and Social Media sites provide yet another vector. Malware may be concealed in files attached to posts or presented as downloads. An attacker may compromise a site so that it automatically infects vulnerable browser software (a drive-by download).
A supply chain is an end-to-end process of designing, manufacturing, and distributing goods and services to customers. Rather than attack a target organization directly, a threat actor may seek ways to infiltrate it via companies in its supply chain.
Ensuring reliable sources of equipment and software is called procurement management. In procurement management, it's helpful to distinguish several types of relationships, such as suppliers, vendors, and business partners.
Suppliers obtain products directly from a manufacturer to sell to other businesses. Vendors receive products from suppliers to sell to retail businesses or directly to customers. The term business partners implies a closer relationship where two companies share closely aligned goals and marketing opportunities. Each of these companies has its own supply chain.
The supply chain breadth and complexity expose organizations to a huge attack surface. For example, a computer motherboard supply chain can include a chip manufacturer, firmware code developer, OEM reseller, courier delivery company, and administrative staff responsible for provisioning the computing device to the end user. Anyone with the time and resources to modify the computer's firmware could create backdoor access. The same applies to any computer or network hardware, software, or service.
Well, that's it for this lesson. In this lesson, we introduced you to multiple attack surface vectors including Vulnerable software vectors, Network Vectors, Lure-based Vectors, Message-based Vectors, and Supply Chain Vectors. Understanding the methods by which threat actors infiltrate networks and systems is essential for you to assess the attack surface of your networks and deploy controls to block attack vectors.

2.1.7 Attack Surfaces Facts

The attack surface is all the points at which a malicious threat actor could try to exploit a vulnerability. Any location or method where a threat actor can interact with a network port, app, computer, or user is part of a potential attack surface. Minimizing the attack surface means restricting access so that only a few known endpoints, protocols/ports, and services/methods are permitted. Each of these must be assessed for vulnerabilities and monitored for intrusions.

This lesson covers the following topics:

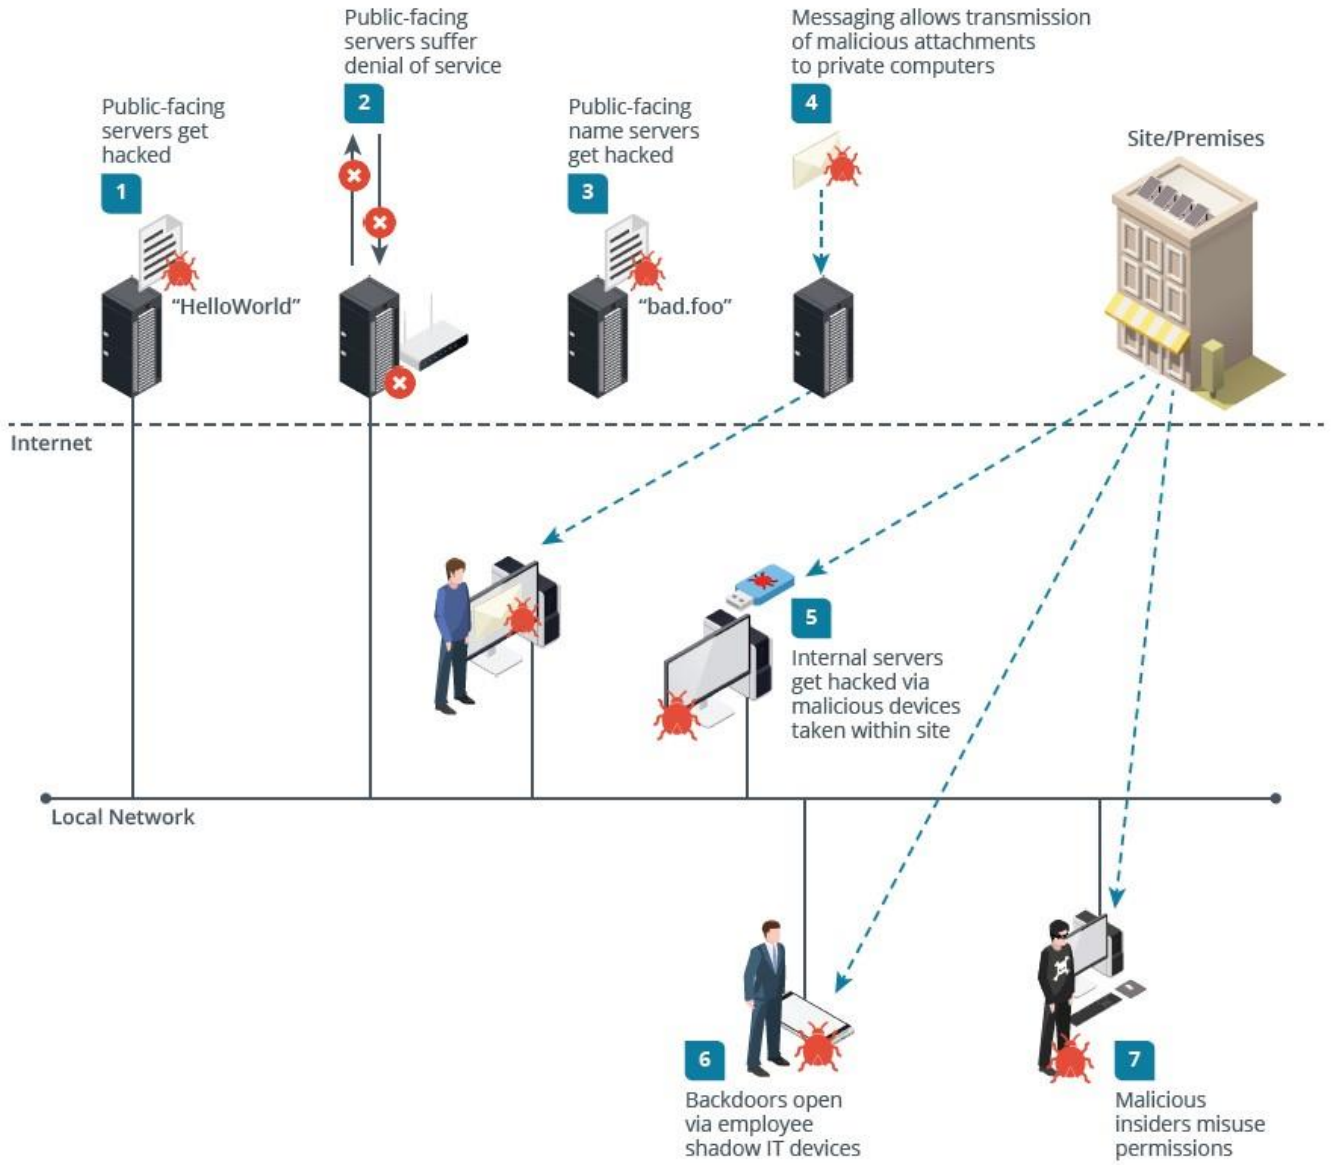
- Attack surface and threat vectors
- Vulnerable software vectors
- Network vectors
- Lure-based vectors
- Message-based vectors
- Supply chain attack surface

Attack Surface and Threat Vectors

An organization has an overall attack surface. You can also assess attack surfaces at more limited scopes, such as that of a single server or computer, a web application, or employee identities and accounts. To evaluate the attack surface, you need to consider the attributes of threat actors that pose the most risk to your organization. For example, the attack surface for an external actor should be far smaller than that for an insider threat.

From a threat actor's perspective, each part of the attack surface represents a potential vector for attempting an intrusion. A threat vector is the path that a threat actor uses to execute a data exfiltration, service disruption, or disinformation attack. Sophisticated threat actors will make use of multiple vectors. They are likely to plan a multistage campaign rather than a single "smash and grab" type of raid. Highly capable threat actors will be able to develop novel vectors. This means the threat actor's knowledge of your organization's attack surface may be better than your own. Developing new threat vectors is one of the capabilities that distinguishes threat actor groups.

The terms "threat vector" and "attack vector" are often taken to mean the same thing. Some sources distinguish the use of threat vector to refer to the analysis of the potential attack surface and attack vector to analyze an exploit that has been successfully executed.



Description (Sample organization attack surface showing hacked servers, denial of service attacks, infected name servers, messaging with malicious attachments, malicious devices, shadow IT devices, and malicious insiders.)

The top row has four servers and a building,representing a company site, above a dotted line labeled as Internet. This indicates they are public facing servers and an organization.

The first two servers and four endpoints have a line connected to another line, below and parallel to the Internet line, labeled Local Network.

All of these devices represent a possible attack surface and there are seven vulnerabilities identified by labels next to the devices.

The first server represents public-facing servers that get hacked. It has a document with a bug icon and the word HelloWorld, refering to the virus by the same name.

The second server has a wireless router next to it and arrows pointing away and toward it. The arrows have red Xs on them indicating that traffic is stopped. It represents public-facing servers suffering denial of service (DoS) attack.

The third server represents public-facing name servers that are hacked. It also has the document and bug icons with the label bad.foo, refering to the DNS virus.

The fourth server has an envelope and bug icon and a dotted line to the first endpoint computer. This represents messaging that allows transmission of malicious attachments to private computers.

The second internal computer has a USB thumb drive near it and a dotted line to the public premises. It represents internal servers that are hacked via malicious devices within the site.

The third endpoint device is a smartphone. This represents backdoors opened via employee shadow IT devices.

Finally, the last endpoint device represents malicious insiders misuse of permissions.

Assessing the attack surface.

Vulnerable Software Vectors

Vulnerable software contains a flaw in its code or design that can be exploited to circumvent access control or to crash the process. Typically, vulnerabilities can only be exploited in specific circumstances and are often swiftly fixed—patched—by the vendor. However, because of the complexity of modern software and the speed with which new versions must be released to market, almost no software is free from vulnerabilities. Also, an organization might not have an effective patch management system. Consequently, vulnerable software is a commonly exploited threat vector.

A large number of operating systems and applications run on a company's appliances, servers, clients, and cloud networks directly increases the potential attack surface. This attack surface can be reduced by consolidating to fewer products and by ensuring the same version of a product is deployed across the organization.

The impact and consequences of a software vulnerability are varied. As two contrasting examples, consider vulnerabilities affecting Adobe's PDF document reader versus a vulnerability in the server software underpinning transport security. The former could give a threat actor a foothold on a corporate network via a workstation; the latter could compromise the cryptographic keys used to provide secure web services. Both are potentially high-impact for different reasons.

Unsupported Systems and Applications

Unsupported systems and applications are a particular reason that vulnerable software will be exposed as a threat vector. An unsupported system is one where its vendor no longer develops updates and patches. Unless the organization can patch the faulty code, these services and apps will be highly vulnerable to exploits.

One strategy for dealing with unsupported apps that cannot be replaced is to try to isolate them from other systems. The idea is to reduce opportunities for a threat actor to access the vulnerable app and run exploit code. Using isolation as a substitute for patch management is an example of a compensating control.

Client-Based vs. Agentless

Scanning software helps organizations automate the discovery and classification of software vulnerabilities. These tools can also be used by threat actors as part of reconnaissance against a target. This scanning software can be implemented as a

client-based agent. The agent runs as a scanning process installed on each host and reports to a management server. Alternatively, the vulnerability management product might use agentless techniques to scan a host without requiring any sort of installation. Agentless scanning is most likely to be used in threat actor reconnaissance.

Network Vectors

Vulnerable software gives a threat actor the opportunity to execute malicious code on a system. To do this, the threat actor must be able to run exploit code on the system or over a network to trigger the vulnerability. An exploit technique for any given software vulnerability can be classed as either remote or local:

- **Remote** means that the vulnerability can be exploited by sending code to the target over a network and does not depend on an authenticated session with the system to execute.
- **Local** means that the exploit code must be executed from an authenticated session on the computer. The attack could still occur over a network, but the threat actor must use some valid credentials or hijack an existing session to execute it.

Consequently, to minimize risks from software vulnerabilities, administrators must reduce the attack surface by eliminating unsecure networks. An unsecure network is one that *lacks* the attributes of confidentiality, integrity, and availability:

- **Lack of Confidentiality** —threat actors are able to snoop on network traffic and recover passwords or other sensitive information. These are also described as *eavesdropping attacks* .
- **Lack of Integrity** —threat actors can attach unauthorized devices. These could be used to snoop on traffic or intercept and modify it, run spoofed services and apps, or run exploit code against other network hosts. These are often described as *on-path attacks* .
- **Lack of Availability** —threat actors are able to perform service disruption attacks. These are also described as *denial of service (DoS) attacks* .

A secure network uses an access control framework and cryptographic solutions to identify, authenticate, authorize, and audit network users, hosts, and traffic.

Some specific threat vectors associated with unsecured networks are as follows:

Threat Vector	Description
Direct access	The threat actor uses physical access to the site to perpetrate an attack. Examples could include getting access to an unlocked workstation, using a boot disk to try to install malicious tools, or physically stealing a PC, laptop, or disk drive.
Wired network	A threat actor with access to the site attaches an unauthorized device to a physical network port, and the device is permitted to communicate with other hosts. This potentially allows the threat actor to launch eavesdropping, on-path, and DoS attacks.
Remote and wireless network	The attacker either obtains credentials for a remote access or wireless connection to the network or cracks the security protocols used for authentication. Alternatively, the attacker spoofs a trusted resource, such as an access point, and uses it to perform credential harvesting and then uses the stolen account details to access the network.
Cloud access	Many companies now run part or all of their network services via internet-accessible clouds. The attacker only needs to find one account, service, or host with weak credentials to gain access. The attacker is likely to target the accounts used to develop services in the cloud or manage

Threat Vector	Description
	cloud systems. They may also try to attack the cloud service provider (CSP) as a way of accessing the victim system.
Bluetooth network	The threat actor exploits a vulnerability or misconfiguration to transmit a malicious file to a user's device over the Bluetooth personal area wireless networking protocol.
Default credentials	The attacker gains control of a network device or app because it has been left configured with a default password. Default credentials are likely to be published in the product's setup documentation or are otherwise easy to discover.
Open service Port	The threat actor is able to establish an unauthenticated connection to a logical TCP or UDP network port. The server will run an application to process network traffic arriving over the port. The software might be vulnerable to exploit code or to service disruption.

Servers have to open necessary ports to make authorized network applications and services work. However, as part of reducing the attack surface, servers should not be configured to allow traffic on any unnecessary ports. Networks can use secure design principles, access control, firewalls, and intrusion detection to reduce the attack surface.

Lure-Based Vectors

A lure is something superficially attractive or interesting that causes its target to want it, even though it may be concealing something dangerous, like a hook. In cybersecurity terms, when the target opens the file bait, it delivers a malicious payload hook that will typically give the threat actor control over the system or perform service disruption.

If the threat actor cannot gain sufficient access to run a remote or local exploit directly, a lure might trick a user into facilitating the attack. The following media are commonly used as lures:

- **Removable Device** —the attacker conceals malware on a USB thumb drive or memory card and tries to trick employees into connecting the media to a PC, laptop, or smartphone. For some exploits, simply connecting the media may be sufficient to run the malware. More typically, the attacker may need the employee to open a file in a vulnerable application or run a setup program.

In a drop attack, the threat actor simply leaves infected USB sticks on office grounds, reception areas, or parking lots, expecting at least one employee to pick one up and plug it into a computer.

- **Executable File** —the threat actor conceals exploit code in a program file. One example is Trojan Horse malware. A Trojan is a program that seems to be something free and useful or fun, but it contains a process that will create backdoor access to the computer for the threat actor.
- **Document Files** —the threat actor conceals malicious code by embedding it in word processing and PDF format files. This can take advantage of scripting features or simply exploit a vulnerability in the document viewer or editor software.
- **Image Files** —the threat actor conceals exploit code within an image file that targets a vulnerability in browser or document editing software.

These vectors expose a large and diverse attack surface, from the USB and flash card readers installed on most computers to the software used to browse websites and view/edit documents. Reducing this attack surface requires effective endpoint security management, using controls such as vulnerability management, antivirus, program execution control, and intrusion detection.

Message-Based Vectors

When using a file-based lure, the threat actor needs a mechanism to deliver the file and a message that will trick a user into opening the file on their computer. Consequently, any features that allow direct messaging to network users must be considered as part of the potential attack surface:

Threat Vector	Description
Email	The attacker sends a malicious file attachment via email or any other communications system that allows attachments. The attacker needs to use social engineering techniques to persuade or trick the user into opening the attachment.
Short Message Service (SMS)	The file or a link to the file is sent to a mobile device using the text messaging handler built into smartphone firmware and a protocol called Signaling System 7 (SS7). SMS and the SS7 protocol are associated with numerous vulnerabilities. Additionally, an organization is unlikely to have any monitoring capability for SMS as it is operated by the handset or subscriber identity module (SIM) card provider.
Instant messaging (IM)	There are many replacements for SMS that run on Windows, Android, or iOS devices. These can support voice and video messaging, plus file attachments. Most of these services are secured using encryption and offer considerably more security than SMS, but they can still contain software vulnerabilities. The use of encryption can make it difficult for an organization to scan messages and attachments for threats.
Web and social media	Malware may be concealed in files attached to posts or presented as downloads. An attacker may compromise a site so that it automatically infects vulnerable browser software (a drive-by download). Social media may also be used more subtly, such as a disinformation campaign that persuades users to install a "must-have" app that is actually a Trojan.

The most powerful exploits are zero-click. Most file-based exploit code has to be deliberately opened by the user. Zero-click means that simply receiving an attachment or viewing an image on a webpage triggers the exploit.

Message-based vectors can also be exploited by a threat actor to persuade a user to reveal a password or weaken the security configuration using some type of pretext. This type of attack might be perpetrated simply by placing a voice call to the user.

Supply Chain Attack Surface

A **supply chain** is an end-to-end process of designing, manufacturing, and distributing goods and services to customers. Rather than attack the target directly, a threat actor may seek ways to infiltrate it via companies in its supply chain. One high-profile example of this is the Target data breach, which was made via credentials held by the company's building systems vendor.

The process of ensuring reliable sources of equipment and software is called procurement management. In procurement management, it is helpful to distinguish several types of relationships:

- **Supplier** —obtains products directly from a manufacturer to sell in bulk to other businesses. This type of trade is referred to as business-to-business (B2B).
- **Vendor** —obtains products from suppliers to sell to retail businesses (B2B) or directly to customers (B2C). A vendor might add some level of customization and direct support.

- **Business Partner** —implies a closer relationship where two companies share closely aligned goals and marketing opportunities.

For example, Microsoft is a major software manufacturer and vendor, but it is not feasible to establish direct relationships with all its potential customers. To expand its markets, it develops partner relationships with original equipment manufacturers (OEMs) and solutions partners. Microsoft operates a program of certification and training for its partners, which improves product support and security awareness.

Each supplier and vendor has its own supply chain. For example, a motherboard manufacturer and supplier will use companies to fabricate individual chip components. The supply chain extends to distribution, so delivery companies and couriers are part of it.

This supply chain breadth and complexity expose organizations to a huge attack surface. For example, for a computer motherboard to be trustworthy, the supply chain of chip manufacturer, firmware code developer, OEM reseller, courier delivery company, and administrative staff responsible for provisioning the computing device to the end user must all be trustworthy. Anyone with the time and resources to modify the computer's firmware could create backdoor access. The same is true for any computer or network hardware, software, or service.

Establishing a trusted supply chain for computer equipment and services essentially means denying malicious actors the time or resources to modify the assets supplied. For most businesses, the use of reputable vendors will represent the best practical effort at securing the supply chain. Government, military/security services, and large enterprises will exercise greater scrutiny. Particular care should be taken if using secondhand machines.

The IT industry also depends on trade in services as well as physical assets. A managed services provider (MSP) provisions and supports IT resources such as networks, security, or web infrastructure. MSPs are useful when an organization finds it cheaper or more reliable to outsource all or part of IT provision rather than try to manage it directly. From a security point of view, this type of outsourcing is complex, as it can be difficult to monitor the MSP. The MSP's employees are all potential sources of insider threat.

2.1.8 Practice Questions (Section Quiz)

q_types_attackers_actor_secp8

Which of the following does a threat actor need in order to support a high-level sophisticated attack?

Answers:

- ***Resources and funding**
- System permissions
- Disinformation
- Data exfiltration

Explanation:

A high level of capability must be supported by resources and funding. Sophisticated threat actor groups need to be able to acquire resources, such as customized attack tools and skilled strategists, designers, coders, hackers, and social engineers. The most capable threat actor groups receive funding from nation-states and organized crime.

An internal/insider threat actor (such as an employee or contractor) has been granted permissions on the system. While permissions might be useful, if a threat actor requires resources and funding, the threat actor is normally external.

Disinformation and data exfiltration are strategies often used by an external threat actor. Data exfiltration transfers a copy of some type of valuable information from a computer or network without authorization. Disinformation falsifies some type of

trusted resource, such as changing the content of a website, manipulating search engines to inject fake sites, or using bots to post false information to social media sites.

q_types_attackers_advanced_secp8

A threat actor successfully breached an advanced corporate network, bypassing multi-factor authentication and intricate intrusion detection systems. The highly coordinated attack leveraged zero-day vulnerabilities and sophisticated custom-made malware.

Which of the following BEST describes the capability level of this threat actor?

Answers:

- ***Advanced**
- Novice
- Intermediate
- Unskilled

Explanation:

The description of the threat actor's actions suggests a high degree of sophistication and technical capability, usually associated with advanced threat actors.

A novice threat actor is typically someone with limited knowledge and hacking skills. The novice threat actor is unlikely to carry out a highly sophisticated attack on an advanced corporate network.

An intermediate threat actor might have some ability to bypass basic security controls. Still, it would be difficult for the actor to carry out a highly sophisticated attack leveraging zero-day vulnerabilities and custom-made malware.

An unskilled threat actor would have limited knowledge and capability to perform sophisticated attacks. The unskilled actor is unlikely to be able to breach an advanced corporate network.

q_types_attackers_apt_secp8

A nation-state developed cyber weapons to achieve military influence and has the ability to obtain and maintain access to compromised networks.

What should a cybersecurity team address when this occurs to their organization's compromised networks?

Answers:

- ***Advanced persistent threats (APT)**
- A hacktivist
- A hacker
- An insider threat

Explanation:

APTs are cyber nation-state adversaries that have developed cybersecurity expertise and use cyber weapons to compromise network security and achieve military and commercial goals.

Hacktivists use cyber weapons to promote a political agenda. They can attempt to obtain and release confidential information to the public domain, perform denial-of-service (DoS) attacks, or deface websites.

Hackers have the skills to gain access to computer systems through unauthorized or unapproved means. The term is sometimes associated with illegal or malicious system intrusion.

Insider threats are employees who harbor grievances or perpetrate fraud. For example, an insider threat might plan and execute a campaign to modify invoices and divert funds.

q_types_attackers_blackmail_secp8

A healthcare provider suddenly receives a threat from an unknown source claiming to have obtained sensitive patient data. The anonymous actor demands a significant sum of Bitcoin, threatening to release the information publicly if the provider does not make payment.

This kind of scenario BEST exemplifies which threat motivation?

Answers:

- ***Blackmail**
- Espionage
- Service disruption
- Disinformation

Explanation:

Blackmail involves threats to reveal damaging information unless the affected party meets the blackmailer's demands, such as demanding Bitcoin for not releasing stolen patient data.

Espionage typically refers to the covert practice of obtaining confidential information for strategic advantage, often conducted by nation-states or competitive companies.

Service disruption prevents an organization from functioning normally through distributed denial-of-service (DDoS) attacks or other means of halting services. The threat scenario mentioned does not include any attempt to halt the healthcare provider's services.

Disinformation refers to the dissemination of false information to deceive or mislead. The threat scenario mentioned does not involve spreading false information but rather the threat of exposing real, sensitive information.

q_types_attackers_data_exfiltration_01_secp8

What type of attack takes content from a local system, encrypts it, and sends it to the attacker's server via HTTP over the port 80?

Answers:

- ***Data exfiltration**
- DDoS attack
- Denial-of-service attack
- Input validation

Explanation:

Data exfiltration is an unauthorized copying or retrieval of data from a system. Data exfiltration attacks are a primary means for attackers to retrieve valuable data often destined for later sale on the black market.

Distributed denial-of-service (DDoS) is an attack that uses multiple compromised computers to launch the attack.

A denial-of-service (DoS) attack causes a service at a given host to fail or to become unavailable to legitimate users.

An input validation attack passes invalid data to the application. The input handling on the routine is inadequate, which causes the application or even the operating system (OS) to behave unexpectedly.

q_types_attackers_data_exfiltration_02_secp8

A threat actor can infiltrate an organization's network and silently extract sensitive proprietary data without detection. The data has a high value on the black market.

Which motivations BEST align with this threat actor's likely objective?

Answers:

- ***Data exfiltration**
- Disinformation
- Service Disruption
- Revenge

Explanation:

Data exfiltration transfers a copy of valuable information from a computer or network without authorization. Threat actors might perform this type of theft because they want the data asset for themselves, can exploit its loss as blackmail, or sell it to a third party.

Disinformation involves falsifying trusted resources, such as changing a website's content or manipulating search engines to inject fake sites.

Service disruption prevents an organization from working as it normally does. It involves an attack on a website or malware-blocking access to servers and employee workstations.

Revenge might involve service disruption or disinformation attacks, but there is no indication in the scenario that the threat actor's motivation was revenge.

q_types_attackers_espionage_secp8

A multinational corporation recently fell victim to a series of cyberattacks, disrupting services and leading to significant financial losses. After an investigation, the corporation found that these attacks were part of a systematic campaign to undermine the corporation's market position.

The highly sophisticated attacks suggest the involvement of a well-resourced entity with specific strategic objectives.

Which of the following motivations BEST describes this scenario?

Answers:

- ***Espionage**

- Revenge
- Financial
- Chaotic

Explanation:

Espionage, characterized by stealthy, long-term breaches, aims at acquiring secret information, often for strategic advantage. The intruders' focus on the proprietary designs and their ability to remain undetected aligns with this motivation.

Revenge motivations typically involve a disgruntled individual seeking retaliation. This scenario does not provide evidence of a personal grievance or individual retaliation.

While financial motivation often involves monetary gain through methods such as blackmail, extortion, or fraud, the primary goal in this scenario is acquiring proprietary information, not explicit financial gain.

Chaotic motivations aim to disrupt for its own sake, often as an act of vandalism or to sow chaos. However, this scenario's targeted, stealthy, and organized nature of the attacks suggests a more sophisticated motivation.

q_types_attackers_financial_gain_secp8

In a recent incident, a hacker group infiltrated a global financial institution's systems and stole the credit card information of millions of customers. The valuable information was soon available on the dark web.

Based on the scenario, what is the MOST likely motivation of the hacker group?

Answers:

- ***Financial gain**
- Philosophical beliefs
- Service disruption
- Ethical concerns

Explanation:

Financial gain is a key motivator for many threat actors. In this scenario, the hacker group's main goal was to profit from the sale of stolen credit card information, which indicates financial gain as the primary motivation.

Philosophical beliefs as a motivation typically involve a group disrupting services or stealing data to pursue their ethical or philosophical beliefs. There is no indication in the scenario that the hacker group's motivation was philosophical.

Service disruption prevents an organization from operating normally, such as by launching a distributed denial of service (DDoS) attack or using malware to block system access.

Ethical concerns are typically associated with whistleblowers or insiders who act out of concern over an organization's unethical behavior.

q_types_attackers_hacker_secp8

Which of the following is the BEST definition of the term *hacker?*

Answers:

- ***A general term used to describe any individual who uses their technical knowledge to gain unauthorized access to an organization.**
- Any individual whose attacks are politically motivated.
- The most organized, well-funded, and dangerous type of threat actor.
- A threat actor whose main goal is financial gain.
- A threat actor who lacks skills and sophistication but wants to impress their friends or garner attention.

Explanation:

The term *hacker* is a general term used to describe any individual who uses their technical knowledge to gain unauthorized access to an organization.

The following are specific types of hackers, also known as threat actors:

- A hacktivist is any individual whose attacks are politically motivated.
- A nation state is the most organized, well-funded, and dangerous type of threat actor.
- An organized crime threat actor is a group of cybercriminals whose main goal is financial gain.
- A script kiddie is a threat actor who lacks skills and sophistication but wants to impress their friends or garner attention. Script kiddies carry out an attack by using scripts or programs written by more advanced hackers.

q_types_attackers_hacktivist_01_secp8

Which of the following threat actors seeks to defame, shed light on, or cripple an organization or government?

Answers:

- ***Hacktivist**
- Script kiddie
- Insider
- Competitor
- Nation state

Explanation:

A hacktivist is any individual whose attacks are politically motivated. Instead of seeking financial gain, hacktivists want to defame, shed light on, or cripple an organization or government. Hacktivists often work alone. Occasionally, they create unified groups with like-minded hackers. For example, the website wikileaks.org is a repository of leaked government secrets, some of which have been obtain by hacktivists.

Script kiddies are usually motivated by the chance to impress their friends or garner attention in the hacking community. Insider threat actors can be motivated by negative feelings toward their employer, bribes from a competitor, or personal financial gain. Competitors could be motivated by financial gain, competitor defamation, or obtaining industry secrets.

There are two primary motives for nation state attacks,seeking to obtain sensitive information (such as government secrets) or seeking to cripple the target's network or infrastructure.

q_types_attackers_hacktivist_02_secp8

A prominent multinational corporation has experienced an unexpected spike in unauthorized network traffic aimed at its web servers. Upon investigation, the corporation discovered that the goal of this traffic was to disrupt its online services rather than gain unauthorized access or steal data.

The attack started shortly after the corporation made a controversial policy decision that sparked a public backlash.

Which type of threat actor is MOST likely responsible?

Answers:

- ***Hacktivist**
- Insider threat
- Individual hacker
- Nation-state

Explanation:

The objective of the attack, disruption of online services following a controversial policy decision, aligns with the typical motives of a hacktivist. Hacktivists often use their skills to promote a social or political cause, which is the most likely the reason for the attack.

Insider threats typically seek to exploit their access to sensitive data or systems for personal gain, which does not align with the motives described in this scenario.

While an individual hacker might have the technical skills to carry out such an attack, the motivations described in the scenario align more closely with a hacktivist.

Nation-state actors typically conduct attacks for strategic or geopolitical gain rather than as a direct response to corporate policy decisions.

q_types_attackers_hacktivist_03_secp8l

A globally recognized fast-food chain recently experienced a cyber attack. The attackers have not shown interest in stealing sensitive data or disrupting operations but have defaced the company's website with messages promoting animal rights and the ethical treatment of livestock.

Based on this information, which type of threat actor is MOST likely responsible for this attack?

Answers:

- ***Hacktivist**
- Insider threat
- Individual hacker
- Nation-state

Explanation:

Hacktivists use their skills to promote a social or political cause. The attackers' objective (in this case, defacing a website to promote animal rights) aligns with typical hacktivist motives.

Insider threats typically involve employees or other individuals with authorized access to systems and information. They usually target sensitive data or disrupt operations for personal gain or revenge, not social or political reasons.

Individual hackers might conduct these types of attacks, but the political and social motives of the attack align more closely with hacktivism.

Nation-state actors are typically motivated by geopolitical strategy, not social or political activism. They tend to target other nations' infrastructure, government systems, or large corporations to steal sensitive data or cause disruption.

q_types_attackers_hacktivist_04_secp8

An environmental advocacy group uses cyber weapons to put companies at risk and promote its agenda.

This scenario illustrates what type of threat actor?

Answers:

- ***Hacktivists**
- Advanced persistent threats (APTs)
- Insider threats
- Hackers

Explanation:

Hacktivists use cyber weapons to promote an agenda, steal confidential information, perform denial-of-service (DoS) attacks, or deface websites. Environmental and animal advocacy groups may target companies in various industries.

APTs are cyber nation-state adversaries that have developed cybersecurity expertise and use cyber weapons to compromise network security and achieve military and commercial goals.

Insider threats are employees who harbor grievances or perpetrate fraud. An insider threat might plan and execute a campaign to modify invoices and divert funds.

Hackers have the skills to gain access to computer systems through unauthorized or unapproved means. The term is sometimes associated with illegal or malicious system intrusion.

q_types_attackers_insider_01_secp8

The IT manager in your organization proposes taking steps to deflect a potential threat actor. The proposal includes the following:

- Create and follow onboarding and off-boarding procedures.
- Employ the principal of least privilege.
- Have appropriate physical security controls in place.

Which type of threat actor do these steps guard against?

Answers:

- ***Insider**
- Script kiddie
- Hacktivist
- Competitor

Explanation:

Because insiders are one of the most dangerous and overlooked threats to an organization, you need to take the appropriate steps to protect against them, such as requiring mandatory vacations, creating and following onboarding and off-boarding procedure, employing the principal of least privilege, and having appropriate physical security controls in place.

A script kiddie is an individual who carries out an attack by using scripts or programs written by more advanced hackers.

A hacktivist is any individual whose attacks are politically motivated.

A competitor threat actor carries out attacks on behalf of an organization and targets competing companies.

q_types_attackers_insider_02_secp8

What type of threat actor is an individual or group with authorized access to an organization's systems and data that can potentially misuse access for malicious purposes?

Answers:

- ***Insider threat**
- Hacktivist
- Nation-state
- Unskilled attacker

Explanation:

Insider threats are individuals or groups with authorized access to an organization's systems and data. They could potentially misuse their access for malicious purposes. Insider threats can include employees, contractors, or any other individuals granted internal access.

Hacktivists are politically motivated cyber attackers. They do not usually have authorized access to an organization's systems or data.

Governments support nation-state actors that engage in highly sophisticated cyberattacks. They typically do not have authorized access to an organization's systems.

Unskilled attackers often use readily available tools to perform cyberattacks and generally do not have authorized access to an organization's systems.

q_types_attackers_insider_03_secp8

What type of threat actor will attempt to exploit their authorized access within an organization for revenge or financial gain?

Answers:

- ***Insider threat**
- Hacktivist
- Nation-state
- Unskilled attacker

Explanation:

Insider threats are individuals or groups with authorized access to an organization's systems and data. They could potentially misuse their access for malicious purposes. Insider threats can include employees, contractors, or any other individuals granted internal access.

Hacktivists are politically motivated cyber attackers. They do not usually have authorized access to an organization's systems or data.

Governments support nation-state actors that engage in highly sophisticated cyberattacks. They typically do not have authorized access to an organization's systems.

Unskilled attackers often use readily available tools to perform cyberattacks and generally do not have authorized access to an organization's systems.

q_types_attackers_insider_04_secp8

An employee suspected of modifying company invoices diverted funds from a company account to their private bank account.

What kind of malicious actor type does this describe?

Answers:

- ***Insider threat**
- Competitor
- Unskilled attacker
- Hacktivist

Explanation:

Insider threats are employees who harbor grievances or perpetrate fraud. An insider threat might plan and execute a campaign to modify invoices and divert funds.

Competitor attacks aim at theft, disrupting a competitor's business, or damaging its reputation. Employees who recently changed companies might facilitate competitor attacks and bring an element of insider knowledge with them.

An unskilled attacker uses hacker tools without understanding how they work or having the ability to craft new attacks. Unskilled attacker attacks have no specific target or reasonable goal other than gaining attention.

Hacktivists use cyber weapons to promote a political agenda. They obtain and release confidential information to the public, perform denial-of-service (DoS) attacks, or deface websites.

q_types_attackers_internal_threat_secp8

A cyber security analyst notices an unusual amount of data transmitted from an employee's company computer to an unknown external IP address. The employee has all necessary permissions to access externally transferred sensitive data.

What type of threat actor is MOST likely responsible for this situation?

Answers:

- ***Internal threat actor**
- Unskilled attacker
- Hacktivist

- Nation-state

Explanation:

An internal threat actor is an individual with permissions on the system, typically an employee or contractor. The scenario describes an employee with legitimate access to the data transmitting it to an unknown external IP address, which suggests that the threat actor is internal.

While an unskilled attacker may have some involvement in this situation, the information provided does not support this conclusion.

A hacktivist is someone who uses hacking as a means of expressing or promoting political or social views.

While nation-state actors can also perpetrate cyberattacks, they are typically external threats that do not usually possess the necessary permissions for data access, as described in the scenario.

q_types_attackers_nation_state_01_secp8

An international financial institution recently discovered a persistent and sophisticated cyber attack. The scale and sophistication of the attack suggest that the threat actor has access to significant resources.

The nature of the attack indicates that the threat actor operates with an extended timeline and appears motivated by strategic advantage rather than immediate financial gain.

Which type of threat actor is MOST likely involved?

Answers:

- ***Nation-state**
- Insider threat
- Hacktivist
- Individual hacker

Explanation:

Nation-state actors have the advanced capabilities, significant resources, and strategic motivations to carry out the sophisticated, long-term attack the financial institution discovered.

An insider threat typically does not have the resources and the persistent motivation to carry out a strategic, long-term attack like the one the financial institution discovered.

While hacktivists are sometimes motivated to target a financial institution, they typically do not have the advanced capabilities or resources to carry out this type of sophisticated attack.

An individual hacker usually lacks the significant resources, extended timeline, and strategic motivations behind this attack.

q_types_attackers_nation_state_02_secp8

Which type of threat actor is MOST likely to engage in cyber espionage with strategic or political motivations?

Answers:

- ***Nation-state**
- Competitors
- Hacktivist
- Organized crime

Explanation:

Nation-state actors often have the support of governments. Their activities, including cyber espionage, are typically motivated by strategic or political reasons.

Competitors might engage in cyber espionage against their rivals but are generally motivated by business competitiveness, not strategic or political reasons.

Hacktivists use hacking to express or promote a political agenda, but they are not typically involved in state-level strategic or political cyber espionage.

Organized crime groups engage in cybercrime activities like financial fraud, blackmail, or extortion for profit. They are typically not involved in strategic or political cyber espionage.

q_types_attackers_opp_secp8

A hacker scans hundreds of IP addresses randomly on the internet until they find an exploitable target.

What kind of attack is this?

Answers:

- Targeted attack
- Insider attack
- Nation-state attack
- ***Opportunistic attack**

Explanation:

In this scenario, the hacker is looking for an easy target and doesn't care what they are attacking. This is considered an opportunistic attack.

If the hacker had been targeting a certain individual, company, organization, or nation, it would have been considered a targeted attack.

An insider attack is accomplished by a threat agent who has authorized access to an organization and either intentionally or unintentionally carries out an attack.

A nation-state attack is accomplished by a threat agent that is a sovereign state who may wage an all-out war on a target and have significant resources and money at their disposal.

q_types_attackers_organized_crime_secp8

Which type of threat actor is MOST likely to engage in cybercrime activities, such as financial fraud, blackmail, or extortion for profit, and often operates across the Internet from a different jurisdiction than their victims?

Answers:

- ***Organized crime**
- Hacktivist
- Nation-state
- Unskilled attacker

Explanation:

Organized crime groups are often involved in cybercrime activities like financial fraud, blackmail, or extortion, seeking any opportunity for profit. They can operate across the Internet from a different jurisdiction than their victims, increasing the complexity of prosecution.

Hacktivists are politically motivated cyber attackers. They do not usually have authorized access to an organization's systems or data.

Governments support nation-state actors that engage in highly sophisticated cyberattacks. They typically do not have authorized access to an organization's systems.

Unskilled attackers often use readily available tools to perform cyberattacks and generally do not have authorized access to an organization's systems.

q_types_attackers_political_01_secp8

A multinational corporation recently fell victim to a series of cyberattacks, disrupting services and leading to significant financial losses. After an investigation, the corporation found that these attacks were part of a systematic campaign to undermine the corporation's market position.

The highly sophisticated attacks suggest the involvement of a well-resourced entity with specific strategic objectives.

Which of the following motivations BEST describes this scenario?

Answers:

- ***Political**
- Financial
- Chaotic
- Revenge

Explanation:

Political motivations typically involve strategic objectives to bring about change or achieve specific goals, often at a societal or governance level. This scenario's systematic, strategic, and sophisticated attacks and the intent to undermine the corporation's market position suggest a political motivation.

While financial motivation often involves monetary gain through methods such as blackmail, extortion, or fraud, this scenario does not highlight any explicit financial gain for the threat actor.

Chaotic motivations generally aim to disrupt for their own sake, often as an act of vandalism or to sow chaos. However, this scenario's systematic and strategic nature of the attacks suggests a more sophisticated motivation.

Revenge motivations typically involve a disgruntled individual seeking retaliation.

q_types_attackers_political_02_secp8

A group of threat actors disrupts the online services of an oil company due to their disagreement with the company's environmental policies. They believe their actions can force the company to change its practices.

This type of threat actor is primarily driven by what kind of motivation?

Answers:

- ***Political/philosophical beliefs**
- Service disruption
- Espionage
- Financial gain

Explanation:

The group, motivated by their philosophical beliefs about environmental responsibility, use their actions to bring about change in line with these beliefs.

Service disruption is a method that threat actors can use to achieve their objectives. In this case, service disruption is the action taken, not the motivation behind it.

Espionage refers to the act of obtaining secret or confidential information without the permission of the holder of the information. In this scenario, there is no mention of the group attempting to obtain confidential information.

The scenario does not suggest that the group's motivation is financial gain. They are not seeking to profit from their actions but to effect change in the company's policies.

q_types_attackers_revenge_secp8

A group of people lost their jobs after their company filed for bankruptcy. These employees formed a closed hacktivist group to fashion a zero-day exploit targeting specific Windows operating systems (OS) on the company network.

They will use internal influences to get the exploit onto the network.

Which of the following factors will greatly influence the success of this attack? (Select two.)

Answers:

- ***Revenge for hardship**
- ***Former colleague assistance**
- Criminal gang threats
- Nation-state influence
- Political motivation

Explanation:

Personal hardship after losing a job can motivate carrying out a revenge attack and seeing it through to the end. Revenge is a common motivator for insider threats.

Former colleagues, who still work for the company, are a good resource to influence and insert a zero-day exploit onto the network. These colleagues (or insider threats) may want to help because they are sympathetic toward the employees who lost their jobs.

Criminal gangs or syndicates will seek any opportunity for criminal profit, but typical activities are financial fraud and extortion against individuals and companies.

Nation-state actors' goals are primarily espionage and strategic advantage over another country. Governments back these actors with virtually unlimited resources.

A political motivation means that the threat actor uses an attack to bring about some type of change in society or governance. This type of motivation does not fit the scenario of employees losing their jobs.

q_types_attackers_service_disruption_secp8

A major online retailer experiences a sudden halt in its services during the peak holiday shopping season. It traces the cause back to an orchestrated distributed denial-of-service (DDoS) attack, which overwhelmed the retailer's servers with traffic, making it impossible for legitimate users to access the site.

This attack BEST aligns with which type of threat motivation?

Answers:

- ***Service disruption**
- Financial
- Disinformation
- Espionage

Explanation:

Service disruption attacks aim to prevent an organization from operating normally. In this case, the distributed denial-of-service (DDoS) attack disrupted the retailer's services.

The effects of the attack might have financial implications for the retailer, but the primary goal was not financial gain for the attackers.

Disinformation involves falsifying trusted resources, such as altering website content or using bots to spread false information. In this scenario, no evidence suggests that the attackers spread false information.

Espionage involves stealthy, long-term breaches aimed at acquiring secret information, often for strategic advantage. The DDoS attack in this scenario does not aim at acquiring any secret information.

q_types_attackers_shadow_it_secp8

The IT department at a large corporation noticed an unfamiliar software application running on its network. Upon investigation, they discovered that a team in the marketing department started using a new cloud-based project management tool to improve their workflow efficiency.

The team did consult with the IT department before implementing this tool.

In the context of cybersecurity threats, what does this situation BEST exemplify?

Answers:

- ***Shadow IT**
- Careless password management

- Insider threat
- Nation-state

Explanation:

Shadow IT refers to hardware, software, and services used within an organization without explicit approval from the IT department. The scenario described, where the marketing team started using a new project management tool without consulting the IT department, is a classic example of Shadow IT.

While this can be a security risk, careless password management refers to using weak passwords or sharing passwords with others.

Insider threat is a potential risk posed by individuals with inside information about the company's security practices, data, and computer systems.

Nation-state activity usually involves cyberattacks conducted by a state or state-sponsored actors against another state or corporation to gather intelligence or disrupt operations.

q_types_attackers_sophistication_secp8

A targeted attack has a budget that can allocate physical and human resources to achieve its goals.

This type of attack contains what attribute?

Answers:

- ***Sophistication**
- Opportunistic
- Unskilled attacker
- Known threats

Explanation:

One must consider an adversaries' sophistication and level of resources and funding. A targeted attack might use highly sophisticated tools backed by a budget that can allocate physical and human resources.

Opportunistic attacks might launch without much sophistication or funding, simply by using tools widely available on the Internet.

An unskilled attacker uses hacker tools without necessarily understanding how they work or having the ability to craft new attacks. Unskilled attacker attacks might have no specific target or any reasonable goal other than gaining attention.

Known threats, such as viruses or rootkits, Trojans, botnets, distributed denial-of-service (DDoS), or specific software vulnerabilities, are relatively straightforward to identify. Organizations can scan for these types of threats with automated software.

q_types_attackers_state_actors_01_secp8

Which malicious actors are likely to show great interest in another country's energy infrastructure and have unlimited resources to carry out espionage attacks?

Answers:

- ***State actors**
- Shadow IT
- Unauthorized hackers
- Semi-authorized hackers

Explanation:

The primary goals of state actors are espionage and strategic advantage. These actors receive government backing, have virtually unlimited resources, and are known to be particular about another country's energy and health network systems.

Shadow IT is an unintentional insider threat where users purchase or introduce computer hardware or software to the workplace with the sanction of their IT department. They do this without a procurement or security analysis process.

Unauthorized hackers have malicious intent. These hackers have limited resources, especially when working alone.

Semi-authorized hackers seek out vulnerabilities in a product or network without seeking approval. After informing companies about vulnerabilities, they do not exploit them but seek voluntary compensation or bug bounty.

q_types_attackers_state_actors_02_secp8

Experts at a scientific facility suspect that operatives from another government entity planted malware and are spying on one of their top secret systems.

Which attacker type is likely responsible based on the attacker's location and likely goals?

Answers:

- ***State actors**
- Criminal syndicates
- Unskilled attackers
- Hacktivists

Explanation:

State actors are responsible for many attacks, particularly on energy and health network systems. They typically work at arm's length from the national government that sponsors and protects them, maintaining plausible deniability.

A criminal syndicate can operate across the internet from a different jurisdiction than its victim, increasing the complexity of prosecution. Syndicates will seek any opportunity for criminal profit, typically financial fraud.

A script kiddie is someone who uses hacker tools without necessarily understanding how they work or having the ability to craft new attacks.

Hacktivists might attempt to obtain and release confidential information to the public domain, perform denial-of-service (DoS) attacks, or deface websites.

q_types_attackers_unskilled_01_secp8

An organization's system alerting tool detects a series of unsuccessful attempts of someone trying to gain unauthorized access to its servers. These attempts lack sophistication and appear to be using publicly available hacking tools.

Which type of threat actor is MOST likely responsible for these attempts?

Answers:

- ***Unskilled attacker**
- Nation-state
- Insider threat
- Hacktivist

Explanation:

Unskilled attackers, often called script kiddies, typically use widely available hacking tools and lack the knowledge to mount sophisticated attacks. The haphazard, unsuccessful attempts described are characteristic of this type of threat actor.

Nation-state attackers are highly sophisticated and typically involved in advanced and well-coordinated cyberattacks, which is not consistent with the pattern of the attempts described.

Insider threats generally have some level of authorized access to the systems, and their attacks do not necessarily follow the pattern of random, unsuccessful attempts described.

Hacktivists typically have a specific political or social agenda, and their attacks often target specific entities or services to further their cause. The described attempts lack any such focus or purpose.

q_types_attackers_unskilled_02_secp8

Which type of threat actor is MOST likely to initiate random, unsophisticated cyberattacks, often utilizing readily available hacking tools without a clear understanding of how they work?

Answers:

- ***Unskilled attacker**
- Nation-state
- Insider threat
- Hacktivist

Explanation:

Unskilled attackers, also known as script kiddies, commonly use widely available hacking tools without fully understanding them. Their attacks are often random and lack sophistication.

Nation-state attackers usually conduct advanced and well-coordinated cyberattacks. They are unlikely to use randomly targeted and unsophisticated attacks.

Insider threats typically have some degree of authorized access to the systems. They do not need simple attack tools; they may misuse their authorized access.

Hacktivists usually have a specific political or social motive. Their attacks typically target particular entities or services to advance their cause. They are not known for random and unsophisticated cyberattacks.

q_types_attackers_war_secp8

A recent cyberattack led to massive disruptions in a country's power grid, causing widespread blackouts and significant economic and social damage. The country's cyber team traced the attack to a hostile nation-state's cyber warfare division.

In this case, what is the primary motivation of the perpetrators?

Answers:

- ***War**
- Financial gain
- Ethical concerns
- Levels of sophistication/capability

Explanation:

In this case, the hostile nation-state attacked to cause widespread disruption and damage, a common objective in warfare. Such acts are a part of the broader strategy of using cyber means to achieve military and political objectives.

Financial gain typically involves stealing data for selling on the dark web, extortion, or fraud.

Ethical concerns generally drive insiders or whistleblowers to act against an organization's unethical behavior. Ethical concerns do not apply to the hostile nation-state's actions, driven by strategic considerations rather than ethical issues.

While the attack demonstrates high sophistication and capability, it is not the primary motivation. Instead, it indicates the actor's resources and skills.

q_att_def_strat_attack_secp8

Match the general attack strategy on the left with the appropriate description on the right. (Each attack strategy may be used once, more than once, or not all.)

Answers:

- Reconnaissance
- Breaching
- Escalating privileges
- Staging
- Exploitation

Explanation:

General attack strategies include the following steps:

- Reconnaissance is the process of gathering information about an organization, including system hardware information, network configuration, and individual user information.
- A breach is the penetration of system defenses. Breaches are achieved using the information gathered during reconnaissance.
- An escalating privileges attack is one of the primary objectives of an attacker, which can be achieved by configuring additional (escalated) rights to do more than breach the system.
- Staging is preparing a computer to perform additional tasks in the attack, such as installing software designed to attack other systems.
- An Exploit is used to take advantage of known vulnerabilities in software and systems. Types of exploitation include stealing information, denying services, crashing systems, and modifying information.

q_att_def_strat_defense_secp8

Match the general defense methodology on the left with the appropriate description on the right. (Each methodology may be used once, more than once, or not all.)

Answers:

- Layering
- Principle of least privilege
- Variety
- Randomness
- Simplicity

Explanation:

General defense methodologies include the following items:

- Layering is the process of implementing multiple security measures to protect the same asset. Defense in depth or security in depth is the premise that no single layer is completely effective in securing the assets. The most secure system/network has many layers of security and eliminates single points of failure.
- When using the principle of least privilege, users or groups are given only the access they need to do their job and nothing more. When assigning privileges, be aware that it is often easier to give a user more access when they need it than to take away privileges that have already been granted.
- Defensive layers should have variety and be diverse. Implementing multiple layers of the exact same defense does not provide adequate strength against attacks.
- Randomness relies on the constant change in personal habits and passwords to prevent anticipated events and exploitation.
- Security measures should provide protection, but not be so complex that you do not understand and use them.

q_att_def_strat_privilege_secp8

Which of the following is the BEST example of the principle of least privilege?

Answers:

- Mary has been given access to all of the file servers.
- ***Wanda has been given access to the files that she needs for her job.**
- Jill has been given access to all of the files on one server.
- Lenny has been given access to files that he does not need for his job.

Explanation:

Wanda being given access only to what she needs to do her job is an example of the principle of least privilege.

The principle of least privilege states that users or groups are given only the access they need to do their jobs and nothing more.

q_att_def_strat_recon_secp8

In which phase of an attack does the attacker gather information about the target?

Answers:

- Escalating privileges
- ***Reconnaissance**
- Breach the system
- Exploit the system

Explanation:

Reconnaissance is the phase of an attack where the attacker is gathering information about the target. This can be done electronically using scanning tools or even physically by going through dumpsters.

Escalation of privileges comes at the end of the attack when the attacker gains access to unauthorized data.

Breaching or exploiting the system is when the attacker gains access to a system on the target network using a vulnerability.

q_att_def_strat_variety_secp8

You have decided to secure your system/network by including several layers of security.

What other defense methodology is recommended that you should you incorporate to these defense layers to enhance security?

Answers:

- ***Variety of methods**
- Simplicity
- Principle of least privilege
- Randomness

Explanation:

Besides securing your system network by including layers of security, the defensive layers should incorporate a variety of methods.

The following are other general defense methodologies that you should consider, but are not as closely tied to enhancing layering:

- Simplicity - Security measures should provide protection but not be so complex that it is difficult to understand and use.
- Principle of least privilege - The principle of least privilege states that users or groups are given only the access they need to do their jobs and nothing more.
- Randomness - Randomness in security is the constant change in personal habits and passwords to prevent predictable behavior.

q_attack_surfaces_bluetooth_secp8

What technique does the threat actor use in a Bluetooth network attack to transmit malicious files to a user's device?

Answers:

- ***Exploiting vulnerabilities or misconfigurations in the Bluetooth protocol**
- Spoofing a trusted access point to gain unauthorized access
- Obtaining credentials for remote access to the network

- Physically stealing a PC or laptop to execute the attack

Explanation:

In a Bluetooth network attack, the threat actor exploits vulnerabilities or misconfigurations in the Bluetooth protocol to transmit a malicious file to a user's device.

Spoofing a trusted access point to gain unauthorized access is not specific to Bluetooth network attacks but relates to the remote and wireless network threat vector.

Obtaining credentials for remote access to the network is also not specific to Bluetooth network attacks but pertains to the remote and wireless network threat vector.

Physically stealing a PC or laptop to execute the attack is part of the direct access threat vector and irrelevant to Bluetooth network attacks.

q_attack_surfaces_conceal_code_secp8

During a cybersecurity attack, how would a threat actor use image files as a lure to target a vulnerability in a browser or document editing software?

Answers:

- ***The threat actor conceals exploit code within an image file that targets a vulnerability in the browser or document editing software.**
- The threat actor conceals malware on a USB thumb drive or memory card and tricks employees into connecting the media to a PC, laptop, or smartphone.
- They may use a program file with concealed exploit code, like Trojan Horse malware, to create backdoor access.
- The threat actor embeds malicious code in word processing and PDF format files to exploit vulnerabilities in document viewer or editor software.

Explanation:

The image file simply serves as a lure. This lure entices the target to open it, thus delivering a malicious payload hook when executed and further triggering the exploit.

A removable device lure conceals malware on a removable device, which will trick employees into connecting it to their individual devices.

Concealing an exploit code in a program file like Trojan Horse malware is an executable file lure.

Embedding malicious code in word processing and PDF format files to exploit document viewer or editor software vulnerabilities is a document file lure.

q_attack_surfaces_direct_access_secp8

A threat actor gains physical access to an organization's premises and attempts to perpetrate an attack on the wired network.

What specific threat vector associated with unsecured networks is likely used by the threat actor in this scenario?

Answers:

- ***Direct access**
- Remote and wireless network
- Bluetooth network
- Default credentials

Explanation:

The threat actor gains physical access to the site, making the direct access threat vector the most relevant choice as it involves using physical access to perpetrate an attack, such as accessing an unlocked workstation or stealing a PC.

Remote and wireless network threat vector involves obtaining credentials for remote access or wireless connection to the network or spoofing a trusted resource like an access point.

Bluetooth network threat vector involves exploiting vulnerabilities or misconfigurations in Bluetooth devices, not gaining physical access to an organization's premises.

Default credentials threat vector refers to gaining control of a network device or app due to default passwords, not due to physical access to the organization's premises.

q_attack_surfaces_infiltrate_secp8

A hacktivist group is intercepting multiple emails between a company and a few vendors and has learned that the company is planning to purchase new laptops and some Universal Serial Bus (USB) thumb drives.

In what ways can the group breach the target company MOST effectively? (Select two.)

Answers:

- ***Infiltrate the shipping company**
- ***Add malicious USB drives**
- Create a fake social media account
- Steal an employee's laptop
- Obtain credentials for remote access to the network

Explanation:

Infiltrating the shipping company takes advantage of the supply chain. In this manner, malicious actors can replace parts of the laptop or hack the operating systems before it gets to the company.

Adding malicious USB thumb drives to the order is taking advantage of removable media to trick the user into plugging them into a computer where the hacker can carry out further attacks.

Creating a fake account on Facebook or LinkedIn takes advantage of social media to carry out social engineering attacks. Hackers can pose as the vendor in this case, but this is not as effective as directly infiltrating the company or adding malicious thumb drives to the order.

Stealing an employee's laptop uses direct access attacks involving physical or local breach techniques at the target person, system, or network. However, this option fails to input compromised assets back into company infrastructure.

Obtaining credentials for remote access to the network can contribute to the efforts, but, given the scenario, is not the most effective way to breach the target company.

q_attack_surfaces_instant_messaging_secp8

You are a cybersecurity analyst at a large organization. You have been tasked with identifying the most secure method of communication to mitigate the risk of message-based vectors.

Which of the following methods would be MOST effective?

Answers:

- Email
- Short Message Service (SMS)
- ***Instant messaging (IM)**
- Web and social media

Explanation:

Instant messaging (IM) is the correct answer. Many instant messaging platforms offer end-to-end encryption, which means that only the sender and the recipient can read the messages. This makes it more difficult for attackers to intercept and read the messages, making instant messaging the most secure method of communication in this list.

While email is a common method of communication in many organizations, it is also a common vector for cyber attacks. Phishing emails, for example, are a common method used by attackers to trick users into revealing sensitive information or downloading malware. Therefore, while email can be made more secure through various measures, it is not the most secure method of communication in this list.

Short Message Service (SMS), or text messaging, is another common method of communication. However, it is also susceptible to various forms of attack, including SMiShing (SMS phishing) and SIM swapping. Like email, while it can be made more secure, it is not the most secure method in this list.

While web and social media platforms are widely used for communication, they are also common targets for cyber attacks. Social engineering attacks, for example, often use social media to trick users into revealing sensitive information. Therefore, while these platforms can be made more secure, they are not the most secure method of communication in this list.

q_attack_surfaces_isolate_apps_secp8

CloudSecure is facing a cybersecurity challenge where some of its critical software applications are no longer supported by vendors, making them vulnerable to potential exploits. The IT team is exploring various strategies to mitigate the risk posed by these unsupported apps.

What is the MOST effective approach to enhance the security posture?

Answers:

- ***Isolating the unsupported apps from other systems to reduce the attack surface.**
- Implementing regular patch management to fix the faulty code.
- Consolidating all operating systems and applications into one product.
- Ignoring the vulnerability as it can only be exploited in specific circumstances.

Explanation:

Isolating the unsupported apps from other systems helps to prevent threat actors from accessing the vulnerable app and running exploit code, thus acting as a compensating control.

Unsupported apps do not receive updates and patches; therefore, regular patch management would not be possible.

Consolidating into one product may not address the central issue of unsupported apps, and it may not be feasible or even practical for the organization's diverse needs.

Ignoring the vulnerability is not recommended, as attackers can exploit it in specific circumstances, potentially causing additional harm to the organization.

q_attack_surfaces_lack_of_integrity_secp8

Which of the following involves threat actors attaching unauthorized devices to a physical network port, allowing them to eavesdrop on network traffic, intercept and modify data, run spoofed services and applications, or execute exploit code against other hosts?

Answers:

- ***Lack of integrity**
- Lack of availability
- Lack of confidentiality
- Lack of authentication

Explanation:

Commonly called on-path attacks, lack of integrity compromises the reliability of the data transmission.

A lack of availability is where the network is vulnerable to service disruption attacks, such as distributed denial-of-service (DDoS) attacks.

Lack of confidentiality results in the exposure of sensitive and private information during data transmission through the open port, making it susceptible to eavesdropping attacks by malicious actors.

A lack of authentication makes it viable for unauthorized users to access the network and its resources without proper credentials, increasing the likelihood of security breaches.

q_attack_surfaces_msp_secp8

CryptoCloud is expanding its business and is considering outsourcing its IT resources to a managed services provider (MSP) to improve efficiency and reliability.

Which of the following statements about MSPs and their role in the supply chain are correct? (Select two.)

Answers:

- ***MSPs may introduce a complex security challenge as monitoring their employees can be difficult.**
- ***MSPs primarily focus on providing support for IT resources such as networks, security, or web infrastructure.**
- MSPs handle the end-to-end process of designing, manufacturing, and distributing goods and services to customers.
- MSPs are only suitable for large enterprises with extensive IT infrastructure and are not recommended for smaller businesses.
- MSPs involves receiving an attachment or viewing an image on a webpage which triggers an exploit.

Explanation:

Outsourcing to an MSP can be complex from a security point of view due to the difficulty in monitoring the actions of the MSP's employees, who are potential sources of insider threats.

MSPs manage, monitor, and maintain the organization's IT infrastructure, applications, and services. Their services can include network management, security, data backup, cloud computing, hardware and software maintenance, help desk support, and other IT-related tasks.

MSPs are suitable for any organization of any size looking to outsource its IT resources.

The primary focus of MSPs is to provide IT resource support rather than handling supply chain logistics.

Zero-click means that simply receiving an attachment or viewing an image on a webpage triggers an exploit.

q_attack_surfaces_supply_chain_secp8

A group of hackers has been monitoring recent orders from a company involving new laptops and Universal Serial Bus (USB) thumb drives. The group infiltrated the shipping company and added malicious USB thumb drives to the order. The target company received the order without any concerns.

What vectors made this attack successful? (Select two.)

Answers:

- ***Supply chain**
- ***Removable media**
- Social media
- Direct access
- Cloud access

Explanation:

Infiltrating the shipping company takes advantage of the supply chain. Malicious actors can replace parts of the laptop or hack the operating systems before it gets to the company.

Adding malicious USB thumb drives to the order takes advantage of removable media to trick the user into plugging them into a computer where the hacker can carry out further attacks.

Creating a fake social media account posing as the vendor to carry out social engineering attacks is not as effective as infiltrating the company or adding malicious thumb drives to the order.

Stealing an employee's laptop uses direct access attacks involving physical or local breach techniques. However, this option fails to input compromised assets back into company infrastructure.

Cloud access involves an attacker finding one or more accounts, services, or hosts with weak credentials in the cloud to gain access to a network. However, in this scenario there is no need to hack the company's cloud.

q_attack_surfaces_vendor_secp8

As a cybersecurity analyst, you are tasked with reducing the supply chain attack surface in your organization.

Which of the following areas should you focus on to MOST effectively mitigate this risk?

Answers:

- Internal IT infrastructure
- Employee training
- ***Vendor management**
- Customer data protection

Explanation:

Vendor management is the correct answer. The supply chain attack surface is often increased by third-party vendors who have access to your organization's systems or data. By focusing on vendor management, including conducting regular security audits and enforcing strict security standards, you can significantly reduce the supply chain attack surface.

While securing the internal IT infrastructure is crucial for any organization, it does not directly address the supply chain attack surface. Supply chain attacks often come from external sources, such as third-party vendors, rather than internal systems.

While employee training is important for overall cybersecurity awareness, it does not directly address the supply chain attack surface. Employees can be trained to recognize and avoid common attack vectors, but this does not mitigate the risk of a compromised vendor.

While protecting customer data is a critical aspect of cybersecurity, it does not directly address the supply chain attack surface. Supply chain attacks often target the organization's systems or data, rather than customer data specifically.

2.2 Social Engineering

As you study this section, answer the following questions:

- What is social engineering?
- What are the phases of a social engineering attack?
- What is pretexting and how is it used in social engineering?
- What are some of the most common social engineering techniques?
- How are motivation techniques effective in convincing targets to comply with a hacker's desires?
- What are common variations of phishing?
- How does a watering hole attack work?

In this section, you will learn to:

- Use the Social Engineer Toolkit.
- Investigate a social engineering attack.
- Identify social engineering.

Key terms for this section include the following:

Term	Definition
Social engineering	An activity where the goal is to use deception and trickery to convince unsuspecting users to provide sensitive data or to violate security guidelines.

Impersonation	A social engineering attack where an attacker pretends to be someone they are not.
Pretexting	A social engineering tactic where a team communicates, whether directly or indirectly, a lie or half-truth in order to get someone to believe a falsehood.
Phishing	An email-based social engineering attack in which the attacker sends email from a supposedly reputable source, such as a bank, to try to elicit private information from the victim.
Vishing	A human-based attack where the attacker extracts information while speaking over the phone or leveraging IP-based voice messaging services (VoIP).
Smishing	A form of phishing that uses SMS text messages to trick a victim into revealing information.
Pharming	A type of attack that redirects users from a legitimate website to a malicious one.
Typosquatting	An attack in which an attacker registers a domain name with a common misspelling of an existing domain, so that a user who misspells a URL in a browser is taken to the attacker's website.
Business email compromise	An impersonation attack in which the attacker gains control of an employee's account and uses it to convince other employees to perform fraudulent actions.
Watering hole attack	An attack in which an attacker targets specific groups or organizations, discovers which websites they frequent, and injects malicious code into those sites.

This section helps you prepare for the following certification exam objectives:

Exam	Objective

CompTIA Security+ SY0-701	2.1 Compare and contrast common threat actors and motivations.
	• Threat actors
	  ○ Unskilled attacker
	  ○ Insider threat
	• Motivations
	
	2.2 Explain common threat vectors and attack surfaces.
	• Human vectors/social engineering
	  ○ Phishing
	  ○ Smishing
	  ○ Vishing

	○ Misinformation/disinformation ○ Impersonation ○ Business email compromise (BEC) ○ Pretexting ○ Watering hole ○ Brand impersonation ○ Typosquatting 5.6 Given a scenario, implement security awareness practices. • User guidance and training ○ Social engineering • Development
TestOut Security Pro	5.0 Audit and Security Assessment 5.2 Assessment Techniques 5.2.2 Identify Social Engineering

2.2.1 Social Engineering Overview (Lesson Video)

Transcript:

A social engineering attack involves human interaction. The attacker tries to trick their victim, convince them to do things, or make them give out information they wouldn't under normal circumstances.

Because this attack involves humans, it's very hard to protect your data and assets against social engineering. It's also much harder to track and catch it before any damage is done. The best way to minimize social engineer's impact is to educate employees, managers, administrators, custodial staff, clients, users, consumers--essentially, the entire planet should learn to recognize and respond appropriately to social engineering attacks.
Social engineers are master manipulators. They're very good at discerning signs and behaviors worth exploiting for information. Some of the tactics that exploit human weakness include moral obligation, innate human trust, threatening, asking for very little, and using ignorance.
If the attacker exploits the victim's willingness to be helpful and assist them out of a sense of responsibility, that's leveraging moral obligation.
If the attacker exploits the victim's natural tendency to trust others, they're taking advantage of innate human trust. The attacker wears certain clothes, creates a certain demeanor, and speaks words and terms the victim is familiar with so they'll trust the attacker and give them what they want.
A threat is when the attacker intimidates the victim by promising negative consequences if they don't comply with the attacker's request.
And attackers will often promise some reward in return for very little to nothing, asking the victim to do a small favor or share a bit of information in return for a huge payoff.
Ignorance means the victim isn't educated in social engineering tactics and prevention, so they can't recognize an attack even when it's happening to them.
Now let's talk about the steps involved in a social engineering attack. These steps can be divided into three main parts: research, development, and exploitation.
The research phase is when the attacker starts gathering information about the company or organization they'll attack. Attackers use a process called footprinting to do this.

This is when the attacker goes through the target company's official websites and social media, performs dumpster diving, searches for employees' names, email addresses, and IDs, goes on a company tour, and conducts other types of on-site observation.
Then he'll move on to the development phase, which has two parts: selecting individual targets within the company being attacked and forming a relationship with the targets.
Usually, attackers choose people who not only have access to the information or object they desire, but show signs of being frustrated, over-confident, or arrogant, or having other traits that make it easy to extract information from them.
Once he's selected his targets, the attacker will start forming a relationship with them through conversations, emails, shared interests, and so on. This builds the victims' trust in the attacker, allowing them to be comfortable and relaxed so that they'll be even more willing to help.
The exploitation phase is when the attacker takes advantage of the relationship with the victim and uses the victim to extract information, obtain access, or accomplish the attacker's purposes in some way. Some examples include disclosing a password and username over the phone; introducing the attacker to other company personnel, providing social proof for the attacker; inserting a USB flash drive with a malicious payload into a company computer; opening an infected email attachment; exposing trade secrets in a discussion with a supposed peer.
If the exploitation is successful, the only thing left to do is wrap things up without raising suspicion. Most attackers tie up loose ends, like erasing digital footprints and ensuring no items or information get left behind. A well-planned and smooth exit strategy is the attacker's goal and their final act in the exploitation phase.
Social engineering is such a prevalent threat because it involves humans. So, let's review the key things to remember about social engineers: skilled attackers will know which human weaknesses to exploit based on people's feelings, emotions, and personalities. They're also detail-oriented, patient observers. They're skilled manipulators and good at forming relationships. The best ones will even clean up their tracks to make sure they won't get caught even if the victim realizes what's happened some time later. And the best defense against social engineers is user education.

2.2.2 Social Engineering Overview Facts

Social engineering refers to an attacker enticing or manipulating people to perform tasks or relay information. Social engineering tries to get a person to do something the person would not do under normal circumstances.

This lesson covers the following topics:

- Social engineering
- Manipulation and motivation
- Social engineering process

Social Engineering

Social engineering refers to the means of either eliciting information from someone or getting them to perform some action for the threat actor. It can also be referred to as "hacking the human." A threat actor might use social engineering to gather intelligence as reconnaissance in preparation for an intrusion or to effect an actual intrusion by obtaining account credentials or persuading the target to run malware. There are many diverse social engineering strategies, but to illustrate the concept, consider the following scenarios:

- A threat actor creates an executable file that prompts a network user for their password and then records whatever the user inputs. The attacker then emails the executable file to the user with the story that the user must open the file and log on to the network again to clear up some login problems the organization has been experiencing that morning. After the user complies, the attacker now has access to their network credentials.
- A threat actor contacts the help desk pretending to be a remote sales representative who needs assistance setting up remote access. Through a series of phone calls, the attacker obtains the name/address of the remote access server and login credentials, in addition to phone numbers for remote access and for accessing the organization's private phone and voice-mail system.
- A threat actor triggers a fire alarm, slips into the building during the confusion, and attaches a monitoring device to a network port.

Manipulation and Motivation

Social engineers are master manipulators and use many techniques to motivate their targets to disclose information. The following table provides common examples of these techniques:

Technique	Description
Moral obligation	An attacker uses moral obligation and a sense of responsibility to exploit the target's willingness to be helpful.
Innate human trust	Attackers often exploit a target's natural tendency to trust others. The attacker wears the right clothes, has the right demeanor, and speaks words and terms the target is familiar with so that the target will comply with requests out of trust.
Threatening	An attacker may try to intimidate a target with threats to make the target comply with a request. This is especially the case when moral obligation and innate human trust tactics are ineffective.
Offering something for very little to nothing	Offering something for very little to nothing refers to an attacker promising huge rewards if the target is willing to do a very small favor. The small favor can include sharing what the target thinks is a very trivial piece of information for something the attacker offers.
Ignorance	Ignorance means the target is not educated in social engineering tactics and prevention, so the target does not recognize social engineering when it is happening. The attacker knows this and exploits the ignorance.
Authority and fear	Authority techniques rely on power to get a target to comply without questioning the attacker. The attacker pretends to be a superior with enough power that the target will comply right away without question. The attacker could also pretend to be there in the name of or upon the request of a superior. Authority is often combined with fear. If an authority figure threatens a target with being fired or demoted, the target is more likely to comply without a second thought.
Social proof	With a social proof technique, the attacker uses social pressure to convince the target that it is okay to share or do something. In this case, the attacker might say, "If everybody is doing it, then it is okay for you to do it, too."
Scarcity	Scarcity appeals to the target's greed. If something is in short supply and will not be available, the target is more likely to fall for it.
Likeability	Likeability works well because humans tend to do more to please a person they like as opposed to a person they do not like.
Urgency	To create a sense of urgency, an attacker fabricates a scenario of distress to convince an individual that action is immediately necessary.
Common ground and shared interest	Common ground and shared interest work because sharing a hobby, life experience, or problem instantly builds a connection and starts forming trust between two parties.

Social Engineering Process

The social engineering process can be divided into three main phases: research, development, and exploitation. The following table describes each phase.

Phase	Description
Research	In the research phase, the attacker gathers information about the target organization. Attackers use a process called *footprinting* , which takes advantage of all resources available to gain information. Footprinting includes going through the target organization's official websites and social media, performing dumpster diving, searching sources for employees' names, email addresses, and IDs, going through a tour of the organization, and other kinds of onsite observation.
Development	The development phase involves two parts: • Selecting individual targets within the organization being attacked. • Forming a relationship with the selected targets. Usually, attackers select people who will not only have access to the desired information or object but also show signs of being frustrated, overconfident, arrogant, or somehow easy to extract information from. Once a target is selected, the attacker will start forming a relationship with the target through conversations, emails, shared interests, etc. The relationship helps build the target's trust in the attacker, allowing the target to be comfortable, relaxed, and more willing to help.
Exploitation	In the exploitation phase, the attacker takes advantage of the relationship with the target and uses the target to extract information, obtain access, or accomplish the attacker's purposes in some way. Some examples include: • Disclosing password and username • Introducing the attacker to other personnel, thus providing social credibility for the attacker • Inserting a USB flash drive with a malicious payload into an organization's computer • Opening an infected email attachment • Exposing trade secrets in a discussion. If the exploitation is successful, the only thing left to do is to wrap things up without raising suspicion. Most attackers tie up loose ends, such as erasing digital footprints and ensuring no items or information are left behind for the target to determine whether an attack has occurred or identify the attacker. A well-planned and smooth exit strategy is the attacker's goal and final act in the exploitation phase.

2.2.3 Social Engineering Techniques (Lesson Video)

Transcript:

Adversaries can use a diverse range of techniques to compromise a security system. A prerequisite of many types of attacks is to obtain information about the network and security system. This knowledge is not only stored on computer disks; it also exists in the minds of people. Employees, contractors, suppliers, and customers represent part of the attack surface of any organization. Collectively, they're part of the attack surface referred to as the human vector.

Social engineering refers to eliciting information from someone or getting them to perform some action for the threat actor. It can also be referred to as "hacking the human." We'll look at some common vectors that highlight how cybercriminals exploit human psychology and communication channels to gain unauthorized access, steal sensitive information, or other goals. Knowing these techniques will help you to develop policies and other security controls to mitigate these risks.

Phishing is a combination of social engineering and spoofing. A phishing message might try to convince the user to perform some action, such as installing disguised malware or allowing a remote access connection. Other types of phishing campaigns use a spoofed website set up to imitate a bank, e?commerce site, or some other web resource that should be trusted by the target. The attacker then emails users of the real website indicating their account must be updated or with a hoax alert or alarm, supplying a link to the spoofed site. When the user authenticates with the spoofed site, their login credentials are captured.

Another variation on phishing is called smishing which uses SMS, or text messages instead of email. It's more difficult to determine if the links are spoofed due to the reduced screen and functionality. However, direct messages to a single contact have a high chance of failure.

Next is vishing, short for "voice phishing," which uses phone calls or voice messages to manipulate individuals under the guise of a trusted entity. One high-profile example happened in 2021 when a branch manager received a call that he thought was from his director asking him to transfer $35 million for an acquisition. The voice on the phone sounded just like his director but was a computer-generated voice.

The next vector is impersonation, which simply means pretending to be someone else. It's one of the basic social engineering techniques. Impersonation is possible when the target can't easily verify the attacker's identity, such as over the phone or via an email message. The classic impersonation attack is for the social engineer to phone into a department, claim they have to adjust something on the user's system remotely, and then get the user to reveal their password.

To make the impersonation more credible, hackers will utilize pretexting. This attack vector involves creating a fabricated scenario (pretext) where they carefully craft a story with convincing or intimidating details. To be successful, they depend on obtaining privileged information about their target. Information that might seem innocuous—such as department employee lists, job titles, phone numbers, diaries, invoices, or purchase orders—can help an attacker penetrate an organization through impersonation.

Another technique that overlaps with impersonation and pretexting is brand impersonation. Brand impersonation occurs when attackers create fake websites, emails, or social media profiles that mimic a legitimate brand's online presence. These fake assets are used to deceive individuals into providing personal information or credentials.

Business email compromise (BEC) is a more sophisticated variation of phishing that also employs impersonation. BEC refers to a sophisticated campaign that targets a specific individual within a company, typically an executive. To perpetrate this type of high-stakes attack, the threat actor might first try to gain control of a legitimate mail account to send the phishing messages. The threat actor is likely to perform reconnaissance to obtain a detailed understanding of the target and the best psychological approach and pretexts to trick them.

Disinformation/misinformation tactics could be used to create fake social media posts or referrers (sites that link to the fake site) to boost search ranking. Disinformation refers to a purposeful motivation to deceive. Misinformation refers to repeating false claims or rumors without the intention to deceive. A disinformation campaign might attempt to get others to repeat and amplify the false facts it creates as misinformation.

A watering hole attack relies on a group of targets that use an unsecured third-party website. For example, a threat actor might discover that the staff running an international e-commerce site might use a local pizza delivery firm. An attacker can compromise the pizza delivery firm's website so that it runs exploit code on visitors. They may be able to infect the computers of the e-commerce company's employees and penetrate the e-commerce company's systems.

Typosquatting means that the threat actor registers a domain name very similar to a real one, such as exannple.com, hoping that users won't notice the difference and assume they're browsing a trusted site or receiving email from a known source. Another technique is to register a hijacked subdomain using the primary domain of a trusted cloud provider, such as onmicrosoft.com. If a phishing message appears to come from example.onmicrosoft.com, many users will be inclined to trust it.

Well, that's it for this lesson. In this lesson, we looked at various ways that cybercriminals exploit human vectors that play on human nature through social engineering. The best defense against these types of attacks is training. Individuals and organizations that understand these methods will be more vigilant and less likely to fall prey to the attackers.

2.2.4 Social Engineering Techniques Facts

Adversaries can use a diverse range of techniques to compromise a security system. A prerequisite of many types of attacks is to obtain information about the network and security system. This knowledge is not only stored on computer disks; it also exists in the minds of employees and contractors. A person with permissions on the system is a potential target of manipulative threat actor techniques known as social engineering.

This lesson covers the following topics:

- Human vectors
- Impersonation and pretexting
- Phishing and pharming
- Typosquatting
- Business email compromise
- Brand impersonation and disinformation
- Watering hole attack

Human Vectors

People—employees, contractors, suppliers, and customers—operating computers and accounts are a part of the attack surface of any organization. Collectively, they are referred to as the human vector. Cybercriminals will attempt to exploit human psychology and communication channels to gain unauthorized access, steal sensitive information, or spread malware. Being able to compare and contrast social engineering techniques will help you lead security awareness training and develop policies and other security controls to mitigate these risks.

Impersonation and Pretexting

Impersonation simply means pretending to be someone else. It is one of the basic social engineering techniques. Impersonation is possible when the target cannot easily verify the attacker's identity, such as over the phone or via an email message. A threat actor will typically use one of two approaches:

- **Persuasive/consensus/liking** —convince the target that the request is a natural one and would be impolite or somehow "odd" to refuse.
- **Coercion/threat/urgency** —intimidate the target with a bogus appeal to authority or penalty, such as getting fired or not acting quickly enough to prevent some dire outcome.

The classic impersonation attack is for the social engineer to phone into a department, claim they have to adjust something on the user's system remotely, and then get the user to reveal their password.

Do you really know who's on the other end of the line? (Image © 123RF.com.)

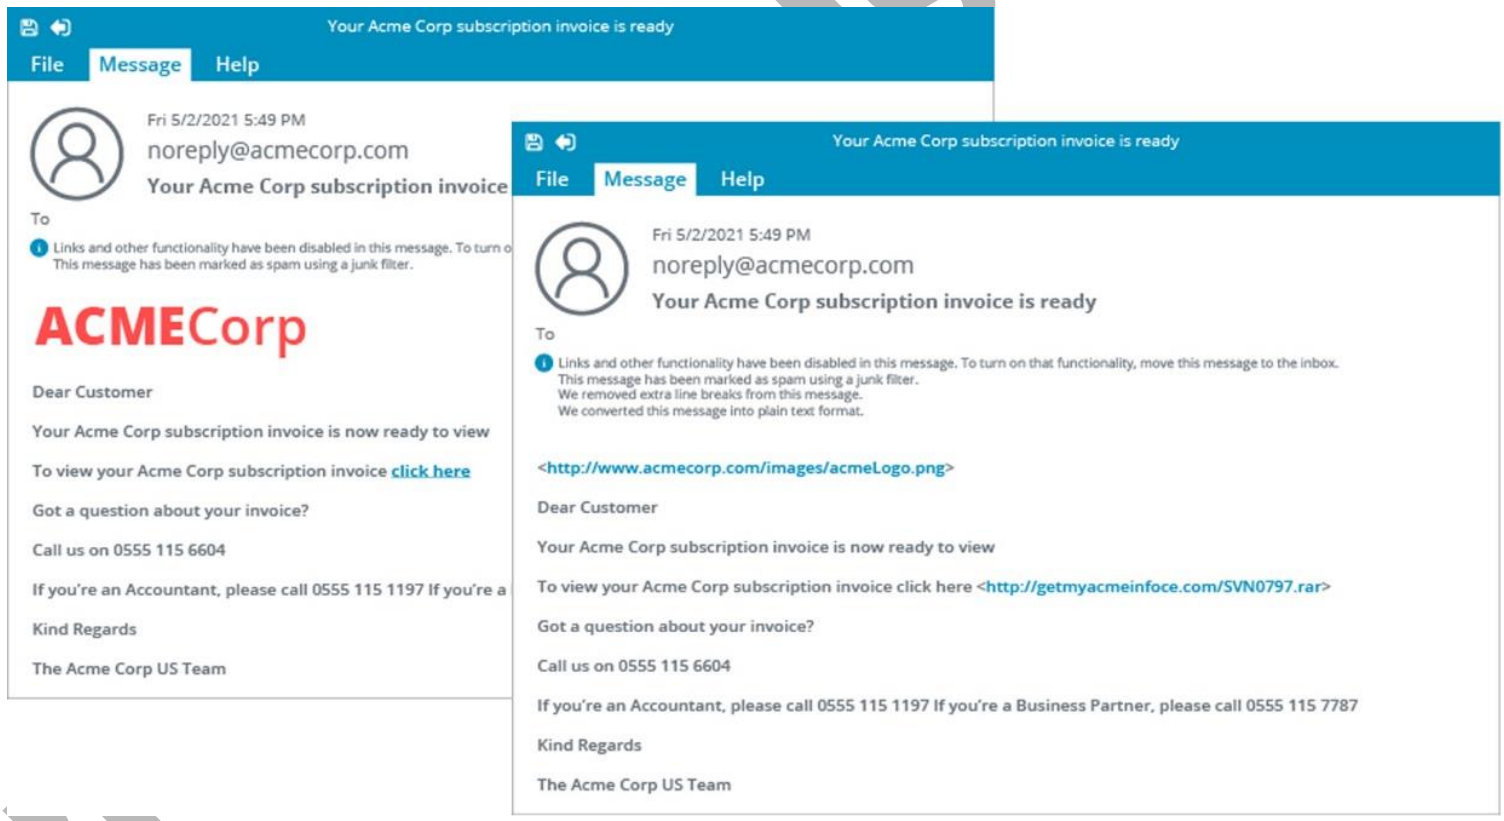
The use of a carefully crafted story with convincing or intimidating details is referred to as **pretexting** . Making a convincing impersonation to either charm or intimidate a target usually depends on the attacker obtaining privileged information about the organization. For example, when the attacker impersonates a member of the organization's IT support team, the attack will be more effective with the identity details of the person being impersonated and the target.

Some social engineering techniques are dedicated to obtaining this type of intelligence as a reconnaissance activity. As most companies are set up toward customer service rather than security, this information is typically quite easy to come by. Information that might seem innocuous—such as department employee lists, job titles, phone numbers, diaries, invoices, or purchase orders—can help an attacker penetrate an organization through impersonation.

Phishing and Pharming

Phishing is a combination of social engineering and spoofing. It persuades or tricks the target into interacting with a malicious resource disguised as a trusted one, traditionally using email as the vector. A phishing message might try to convince the user to perform some action, such as installing disguised malware or allowing a remote access connection by the attacker.

Other types of phishing campaigns use a spoof website set up to imitate a bank or e-commerce site, or some other web resource that should be trusted by the target. The attacker then emails users of the genuine website to inform them that their account must be updated or with a hoax alert or alarm, supplying a disguised link that actually leads to the spoofed site. When the user authenticates with the spoofed site, their login credentials are captured.



Example phishing email—On the right, you can see the message in its true form as the mail client has stripped out the formatting (shown on the left) designed to disguise the nature of the links.

Phishing refers specifically to email or text message threat vectors. The same sort of attack can be performed over other types of media:

- Vishing — a phishing attack conducted through a voice channel (telephone or VoIP, for instance). For example, targets could be called by someone purporting to represent their bank, asking them to verify a recent credit card transaction and requesting their security details. It can be much more difficult for someone to refuse a request made in a phone call than one made in an email.
- SMiShing — a phishing attack that uses Simple Message Service (SMS) text communications as the vector.

Rapid improvements in deep fake technology are likely to make phishing attempts via voice and even video messaging more prevalent in the future.

Direct messages to a single contact have a high chance of failure. Other social engineering techniques still use spoofed resources, such as fake sites and login pages, but rely on redirection or passive methods to entrap victims.

A pharming attack redirects users from a legitimate website to a malicious one. Rather than using social engineering techniques to trick the user, pharming relies on corrupting how the victim's computer performs internet name resolution so that they are redirected from the genuine site to the malicious one. For example, if mybank.foo should point to the IP address 2.2.2.2, a pharming attack would corrupt the name resolution process to make it point to IP address 6.6.6.6.

Typosquatting

Phishing and pharming both depend on impersonation to succeed. The spoofed message or site must appear to derive from a source that the target trusts. A threat actor can use various inconsistencies in how the message's source is represented in a mail client to trick the target into trusting the message source.

Email client software does not always identify the actual email address used to send the message. Instead, it displays a "From" field where a threat actor can add an arbitrary value. This technique is less common now as filtering software can be configured to alert the user to any discrepancy between the actual and claimed sender addresses.

Typosquatting means that the threat actor registers a domain name very similar to a real one, such as exannple.com , hoping that users will not notice the difference and assume they are browsing a trusted site or receiving email from a known source. These are also referred to as *cousin, lookalike,* or *doppelganger* domains.

Another technique is to register a hijacked subdomain using the primary domain of a trusted cloud provider, such as onmicrosoft.com . If a phishing message appears to come from example.onmicrosoft.com , many users will be inclined to trust it.

Business Email Compromise

Where phishing is typically associated with mass mailer attacks, **business email compromise** refers to a sophisticated campaign that targets a specific individual within a company, typically an executive or senior manager. The threat actor poses as a colleague, business partner, or vendor. The threat actor is likely to perform reconnaissance to obtain a detailed understanding of the target and the best psychological approach and pretexts to trick them. They are unlikely to use obvious features of mass mailer phishing messages such as spoofed links or malware file attachments.

To perpetrate this type of high-stakes attack, the threat actor might first try to gain control of a legitimate mail account to send the phishing messages.

Some sources use the term "business email compromise" to mean an attack with a specific financial motivation, where the objective is to persuade a budget holder to authorize a fraudulent payment or wire transfer. Similar terminology for highly targeted attacks includes spear phishing, whaling, CEO fraud (impersonating the CEO), and angler phishing (using social media as the vector).

Brand Impersonation and Disinformation

Brand impersonation means the threat actor commits resources to accurately duplicating a company's logos and formatting (fonts, colors, and heading/body paragraph styles) to make a phishing message or pharming website a visually compelling fake. The threat actor could even mimic the style or tone of email communications or website copy. They could try to get a phishing site listed high in search results using realistic content. **Disinformation/misinformation** tactics could be used to create fake social media posts or referrers (sites that link to the fake site) to boost search ranking.

Disinformation refers to a purposeful motivation to deceive. Misinformation refers to repeating false claims or rumors without the intention to deceive. A disinformation campaign might attempt to get others to repeat and amplify the false facts it creates as misinformation.

Watering Hole Attack

A watering hole attack relies on a group of targets that use an unsecured third-party website. For example, staff running an international e-commerce site might use a local pizza delivery firm. A threat actor might discover this fact through social engineering or other reconnaissance of the target. An attacker can compromise the pizza delivery firm's website so that it runs exploit code on visitors. They may be able to infect the computers of the e-commerce company's employees and penetrate the e-commerce company systems.

It is also important for everyone to be aware of what they post on their own social media platforms. That information can also be used to create more believable impersonations or attacks. As artificial intelligence, machine learning, or other technologies improve, they can be used to create what's known as deep fakes. Deep fakes create media that looks and or sounds like someone making statements that the person did not make or doing something in a picture or video that did not happen.

2.2.5 Use the Social Engineer Toolkit (Demo Video)

Transcript:

In this demo, we're going to talk about how to capture user credentials from a web page. While there are many different methods for gaining unauthorized access to a user's web account, we're going to do it by cloning a website's sign-in page and directing the user to enter the information on a fake page. To fool a user into going to our cloned sign-in page, we would create a phishing email and send it to them.

But in this demo, we're just going to cover cloning. To do this, we will use one of the many exploits provided by the Social Engineering Toolkit. Because this is a demo, we're going to use a fake website. I'll enter the credentials myself to show how the tool works.
First, we need to find a website that we would like to attack, But since we'll only be cloning one page of the site, we need to know what the full URL is for the login page. Let's go to www.fakewebsite.com. This is a Wordpress site, which makes our life a little easier, since the login page name is almost always the same. To make sure, though, we'll click the login button on the page and see where it takes us. I'll scroll down here and click Log in.
Now that we're on the login page, we can look in the address field and see the full URL of the exact page we want to clone. Since we'll need this URL later, we're going to copy it.
Now that we have the page we want to clone, let's open up the Social Engineering Toolkit. Since it's a command-line app, we'll be working in the terminal. Once the terminal opens, I'll type in 'setoolkit' and press Enter. On this screen, you can see that there are two attack options, Social Engineering Attacks and Penetration Testing. If you add extra attacks made by others, they'll appear under Third Party Modules. The remaining options are for maintaining the Social Engineering Toolkit. The option that we're looking for can be found under Social Engineering Attacks. So, I'll select number 1 and press Enter. We're interested in cloning a website, so we'll select option 2, Website Attack Vectors. To get to the clone option from here, we'll select number 3, Credential Harvester Attack Method, and then number 2, Site Cloner. Since we'll be using this machine to host the cloned page and listen for credentials, we can leave the default options. I'll just press Enter to continue.
Next, we'll use Ctrl+Shift+V to paste the URL we copied earlier and press Enter again. Now the Social Engineering Toolkit is saying, "Hey, do you understand what we're saying here?" Yes, yes I do. It also offers a couple of troubleshooting instructions in case the tool isn't working. Since we expect it to work, we'll just press Enter to continue.

Now we're finally at the page that will show us if the tool sees anything interesting. Earlier, I set up a website with a name that's just a little different from the name of the website we're cloning. This is the page that you would send to someone to try to trick them into opening it. It's basically the same address, but with the number 1 at the end. Let's go to that page in our web browser. I'm going to keep the terminal open on the side and open the web browser on the other side of the screen so you can see the tool working. I'll do that by opening Firefox and navigating to www.fakewebsite1.com. You can see that when I navigated to the cloned web page, something happened over to the right in the tool. It printed some information to the screen. This just shows that a connection request that was served to the requesting computer.
Now let's see what happens if I put in some user credentials. I'll type in 'admin' for the user and 'letmein' for the password. Press Enter to log in. And there we go. In the terminal, you can see some more information from the tool. Note that the tool tries to guess what information is important. This time, it correctly identified the password field, but didn't find a username field. That's because Wordpress username fields have kind of ambiguous names. But that didn't get in our way--this information was caught, as you can see right over here. It's worth noting that, after an attempted authentication, the Social Engineering Toolkit actually redirected us to the real website. This means that, typically, a user would likely just assume that they had entered their credentials incorrectly and try again. They probably wouldn't suspect a thing.
And that's it for this demo. We discussed how to use the Site Cloner in the Social Engineering Toolkit, and we saw how you--or anyone--can clone a website's look and feel and trick users into entering their credentials on a fake website.

2.2.6 Investigating a Social Engineering Attack (Demo Video)

Transcript:

In this demonstration, we'll talk about investigating a social engineering attack. We're going to focus on identifying the validity of emails, identifying the validity of websites, and identifying virus hoaxes.

Let's take a look at email validity. You should always be wary of emails from unknown organizations or senders. Be careful opening them, and be even more cautious with their attachments. A lot of hoax emails are pretty easy to spot because of their bad spelling and terrible grammar, but some of them look very, very real. Let's take a look at a couple of examples.
Let's start with this first one, Final Notice, Postal Status Notification. The first clue is the return address. It's from a variation of a Walmart address. It could be legit, but I'm not so sure. Next is the logo. It has a logo with a question mark after the word Walmart. I've never seen a Walmart logo like this, so I really wouldn't have to go any further to know it's a fake. If I hover over the logo, a bunch of addresses pop up. This looks like a batch of addresses that were spammed from this email. A little lower, when I hover over the Update Your Address Here link, I see a bunch more addresses. No legitimate email is going to be formatted to do this. Finally, here, it tells me to hurry, or I'll lose 17% of the money owed to me.
Let's look at this other one, the Check Your Account email. The address looks a bit odd. That's always the first clue. They want to confirm my information. I've never heard of this company, and I don't gamble, so within a second, I know this is fake. These links down here are Bitl.ly, which is a URL shortening service. I don't think most legitimate emails would use a shortening service like this.
Then we have another email that I took a screenshot of. It's this Attention email that says it's from usafed.gov. This is someone posing as somebody from the US Treasury. They're using a Gmail address for communication, which the government wouldn't do. At the bottom of the email, they've listed the legitimate website for the Department of the Treasury to make you think this is a legitimate email.
Another way you can verify an email is by taking a look at the header information. I have my Walmart email opened up in Outlook. This is another way to verify an email and its content. The header information is helpful because it shows IP information for the path an email took from its origin to the destination. It also shows other information, like the mail client that was used, the actual email address of the sender, and the originating IP address of the email.
There are a few ways to look at header information. In Outlook, it's helpful, but not easy to read. If we go into File > Properties, you can see the header information right here. As you can tell, this can't be resized, and it's hard to read in this format. The mail client in Windows 10 doesn't have a way to view header information, but don't worry. You can view header information by opening the email in a text editor like I've done with Notepad++.
By looking through the email in this format, you can pick out many things about its origin and determine whether it's legitimate. Remember, this email was supposed to be from Walmart. Here's the sender's originating IP. If we highlight this address and copy it, we can actually look up some information on that IP address to see where it's coming from.

All internet IP addresses for users come from some ISP somewhere. We can go to a website called arin.net, go to the search, and paste in our address. It'll find some information about this IP address. There are services that you can pay for that will give you a lot more information, but this one is free and simple. Looking at this information, I'm very skeptical that this email came from Walmart because the mailing address for this IP is from France.
Another thing we want to talk about is verifying websites. The first thing that you should always do is double-check the spelling of the website you're navigating to. If you're trying to go to PayPal and the address you end up at is paypals.com (with an s) or paypal.fakesight.com, then you're likely in the wrong place. You could accidentally give away your login information for PayPal (or a similar site) by entering it into a false site. You could also verify a site by viewing the SSL certification information. An SSL certificate (Secure Sockets Layer certificate) is a digital certificate that authenticates the identity of a website and encrypts the information sent to its server using SSL technology.
Let's look at two different browsers, Google Chrome and the Microsoft Edge browser. If we open both of these, there's a slight difference in how the SSL certificates are shown. In the Chrome browser, if you click on the lock in the address bar, it shows information about the certificate. I see that it's issued to google.com. I have a few tabs up here, Details and Certification Path. Under Certification Path, I see more information about the Certificate Authority and the certificate.
Now, if you go to Edge, open up Gmail, and click on the little lock, it'll show you the same information, but in a slightly different format. If there's no lock and no SSL certificate, you should be a little more cautious. Certificates aren't the focus of this lesson, but you want to make sure you know how to verify certificate information when you're not sure about a website.
Our last topic is identifying virus hoaxes. You've probably seen something like this before. Maybe one of your coworkers has come to you in a panic, worried about this type of error, and it's obviously very alarming. It's meant to be; this hoax is designed to scare or intimidate users into thinking they've contracted some type of virus. Normally, it says it's something like a Trojan, as you can see here. Often, there's a number you can call where they'll take payment over the phone for fixing the virus, but they never actually do anything.
There have been similar hoaxes that use the same tactics, so it's good to understand that viruses don't usually want to be discovered. Unless you're being notified by a trusted antivirus software that you or your administrator has installed, then it's probably just a hoax.
That's it for this lesson. We discussed verifying emails by looking at the HTML version and header information. We talked about verifying that a website is correct by checking the spelling of the address and the presence of a valid SSL certificate. We finished by discussing virus hoaxes.

2.2.7 Identify Social Engineering (Simulation)

Scenario

You work as the IT security administrator for a small corporate network in the United States of America. The company president has received several questionable emails that he is concerned may be malicious attacks on the company.

He has asked you to determine whether the emails are hazardous and to handle them accordingly.

In this lab, your task is to:

- Read each email and determine whether it is legitimate.
- Delete any emails that are attempts at social engineering.
- Keep emails that are safe.

Hold your mouse over the embedded links to see the actual URL in the status bar at the bottom of the screen.

Explanation

Complete this lab as follows:

1. From the Inbox of the WebEmail interface, highlight an email.
2. Read and explore the email and determine whether it is a legitimate email. This includes using your mouse to hover over suspicious attachments and links.
3. Take the appropriate action for each email:
    - If the email is an attempt at social engineering, from the menu bar, select **Delete** .
    - If the email is safe, do nothing.
4. Repeat steps 1 through 3 for each email. The following table lists the actions you should take for each email.

Email	Diagnosis	Action	Explanation for Action
Microsoft Windows Update Center New Service Pack	Phishing	Delete	This email has various spelling errors. The link does not direct you to a Microsoft website.
Joe Davis Re: Lunch Today?	Malicious Attachment	Delete	This email appears to be from a colleague; however, why would he fail to respond to your lunch question and send you a random attachment in return?
Executive Recruiting Executive Jobs	Whaling	Delete	Whaling uses tailored information to attack executives. Clicking the link could install malware that would capture sensitive company information. The link is pointing to a site in Germany (.de). It is suspicious that this organization would recruit executives from the USA.
Human Resources Ethics Video	Safe	Keep	While this email has an embedded link, it is digitally signed, as indicated by the green shield and checkmark. Therefore, you know it actually comes from your Human Resources department. When you hover over the link, you see that it is a secure link to the corporate web server.
Online Banking Department Payment Pending	Phishing	Delete	This is a carefully crafted attempt to get your bank account information. Hover over the link and notice that it does not direct you to your credit union website but to an unknown IP address. It is also very unlikely that a bank would delete your account for not verifying your information.

Grandma Jacklin FW: FW: FW: Virus Attack Warning	Hoax	Delete	Any email that asks you to forward it to everyone you know is probably a hoax. This email also contains very bad grammar.
Emily Smith Web Site Update	Spear Phishing	Delete	While this email appears to come from a colleague, notice that the link points to an executable file from a Russian domain name (.ru). A report file is more likely to have an extension of .pdf. .docx, .xlsx, or .txt. This probably is not a message a real colleague would send. This file will likely infect the computer with malware.
Sara Goodwin Wow!!	Malicious Attachment	Delete	Emails with attachments from unknown people who address you as "Dear Friend" are probably not safe.
Grandma Jacklin Free Airline Tickets	Hoax	Delete	Any email that asks you to forward it to everyone you know is probably a hoax, even if the contents promise you a prize. In addition, there is no way to know how many people the email has been forwarded to. Likewise, it is very unlikely that an airline would give away that many free tickets.
Human Resources IMPORTANT NOTICE-Action Required	Safe	Keep	While this email appears very urgent, it doesn't ask you to click on anything or run any attachments. It does inform you that you need to go to a website that you should already know and make sure your courses are complete.
Activities Committee Pumpkin Contest	Safe	Keep	This email doesn't ask you to click on anything or run any attachments.
Robert Williams Presentation	Safe	Keep	This email doesn't ask you to click on anything or run any attachments.

2.2.8 Social Engineering Techniques

2.2.9 Practice Questions (Section Quiz)

q_social_engr_ovw_authority_secp8

An organization's receptionist received a phone call from an individual claiming to be a partner in a high-level project and requesting sensitive information.

The individual is engaging in which type of social engineering?

Answers:

- Urgency
- Social proof
- Common ground
- ***Authority**

Explanation:

Authority social engineering entails an attacker either lying about having authority or using their high status in a company to force victims to perform actions that exceed their authorization level.

Urgency social engineering entails creating a sense of urgency, such as an attacker fabricating a scenario of distress to convince an individual that action is immediately necessary.

Social proof entails using social pressure to convince the target that it's okay to share or do something. For example, the attacker might say, "If everybody is doing it, then it's okay for you to do it, too."

Common ground social engineering entails establishing common ground and shared interest. This approach can be very effective because sharing a hobby, life experience, or problem instantly builds a connection and starts forming trust between two parties.

q_social_engr_ovw_dev_secp8

Ron, a hacker, wants to get access to a prestigious law firm he has been watching for a while. June, an administrative assistant at the law firm, is having lunch at the food court around the corner from her office.

Ron notices that June has a picture of a dog on her phone. He casually walks by and starts a conversation about dogs.

Which phase of the social engineering process is Ron in?

Answers:

- Research phase
- Exploitation phase
- ***Development phase**
- Elicitation phase

Explanation:

The development phase involves two parts. These are selecting individual targets within a company and forming a relationship with those individuals.

The exploitation phase is when the attacker takes advantage of the relationship with the victim and uses the victim to extract information, obtain access, or accomplish the attacker's purposes in some way.

The research phase is when the attacker starts gathering information about the target company or organization.

Elicitation is a technique used to extract information from a target without arousing suspicion.

q_social_engr_ovw_exploitation_secp8

You are a cybersecurity analyst at a large corporation. You notice that a particular employee has been receiving emails from an unknown sender who claims to be a new colleague from a different department.

The sender has been engaging in friendly conversation, asking about the employee's role, and subtly inquiring about certain company processes. Recently, the sender asked the employee to open an attachment that supposedly contains a funny meme.

What phase of the social engineering process does this scenario represent and what should be your immediate action?

Answers:

- Research phase - Inform the employee about the potential threat and advise them to stop communication.
- Development phase - Report the incident to the IT department for further investigation.
- ***Exploitation phase - Isolate the employee's system and conduct a thorough security scan.**
- None of the above - This is a normal interaction and no action is required.

Explanation:

The exploitation phase is the correct answer. The attacker is in the exploitation phase, where they are attempting to use the relationship they've built with the employee to achieve their goal, in this case, by trying to get the employee to open a potentially malicious attachment. The immediate action should be to isolate the employee's system and conduct a thorough security scan to check for any threats.

The research phase is incorrect because the research phase typically involves the attacker gathering information about the target organization, not directly interacting with an employee.

The development phase is incorrect because the development phase involves the attacker forming a relationship with the target, which has already occurred in this scenario. The attacker has moved beyond this phase by attempting to get the employee to open a potentially malicious attachment.

Taking no action is not correct. The scenario described is not a normal interaction and represents a potential security threat. It's important to take immediate action to prevent any potential harm to the organization's systems and data.

q_social_engr_ovw_intim_secp8

Social engineers are master manipulators.

Which of the following are tactics they might use?

Answers:

- ***Moral obligation, ignorance, and threatening**
- Shoulder surfing, eavesdropping, and keylogging
- Eavesdropping, ignorance, and threatening
- Keylogging, shoulder surfing, and moral obligation

Explanation:

Social engineers are master manipulators. Some of the most popular tactics they use are moral obligation, innate human trust, threatening, an easy reward, and ignorance.

Social engineering attacks include shoulder surfing, eavesdropping, USB and keyloggers, spam and spim, and hoaxes.

q_social_engr_ovw_princ_secp8

Any attack involving human interaction of some kind is referred to as what?

Answers:

- An opportunistic attack
- Attacker manipulation
- ***Social engineering**
- A white hat hacker

Explanation:

Social engineering refers to any attack involving human interaction of some kind. Attackers who use social engineering try to convince a victim to perform actions or give out information they wouldn't under normal circumstances.

An opportunistic attack is typically automated and involves scanning a wide range of systems for known vulnerabilities, such as old software, exposed ports, poorly secured networks, and default configurations.

A white hat hacker helps companies find vulnerabilities in their security infrastructure.

Social engineers are master manipulators and use multiple tactics on their victims.

q_social_engr_ovw_scarcity_secp8

As a security officer in a large corporation, you receive an email from an unknown sender claiming to be a high-ranking executive from another branch of your company. The email states that due to a sudden surge in demand for your company's product, there is a shortage of supply.

The sender requests immediate access to your inventory data to assess the situation and promises a significant bonus for your prompt cooperation. The sender also mentions that this is a confidential matter and should not be discussed with anyone else.

What would be the BEST response in this scenario?

Answers:

- Immediately provide the requested data to help the company in this crisis.
- ***Report the email to your supervisor and the IT department without responding to the sender.**
- Respond to the sender asking for more details about the situation.
- Ignore the email as it does not concern your department.

Explanation:

Reporting the email to your supervisor and the IT department without responding to the sender is the best response. The email has several red flags that suggest it could be a social engineering attack. The sender is unknown, the request is urgent, confidential, and involves access to sensitive data. The promise of a bonus is a form of the scarcity technique. It's important to report such incidents to your supervisor and IT department for further investigation.

It is not advisable to share sensitive data without verifying the identity of the requester, even if they claim to be from your company. The promise of a significant bonus and the urgency of the situation are tactics often used in social engineering attacks, specifically the scarcity technique.

Responding to the sender asking for more details about the situation is not advisable because engaging with the sender could potentially expose your system to further risk. It's best to report the incident to the appropriate parties within your organization.

Ignoring the email is not the best course of action because it leaves the potential threat unaddressed. It's important to report such incidents to help your organization stay aware of potential security threats.

q_social_engr_ovw_social_example_secp8

Which of the following is an example of a social engineering attack?

Answers:

- ***A call from a threat actor posing as a remote sales representative to obtain the login credentials to a remote access server from the help desk.**
- An employee sends information to HR, but an attacker secretly intercepts and manipulates the communication, unbeknownst to both employees.
- An attacker floods a website's server with fake requests, making it slow or unresponsive to legitimate users.
- A fake bank email is sent to recipients asking them to update their account info via a link that leads to a fake site, capturing login details.

Explanation:

The example illustrates a social engineering attack where the threat actor deceives the help desk into providing sensitive information through a persuasive phone call.

The scenario is a man-in-the-middle attack focused on both intercepting and relaying communications, which is not present in this scenario.

This answer choice is an example of a denial-of-service attack. This type of attack causes service disruptions.

This scenario is a phishing attack that uses a combination of social engineering and spoofing to persuade or trick the target into interacting with a malicious source disguised as a trusted one.

q_social_engr_ovw_social_proof_secp8

You decided to purchase a natural medication online based on testimonials from several customers.

Later you hear from a news report that the company selling the product has been indicted for fraud. As part of the charges, the testimonials were found to be fake.

Which of the following motivation techniques did the company use to entice you to purchase the natural medication?

Answers:

- ***Social proof**
- Authority
- Urgency
- Scarcity

Explanation:

With a social proof technique, the attacker uses social pressure to convince the target that it is okay to share or do something. For example, the attacker might say, "If everybody is doing it, then it's okay for you to do it, too." In this scenario, the social proof technique the company utilized was fake customer testimonials.

The following are additional motivational techniques that do not fit the scenario:

- Authority - Authority techniques rely on power to get a target to comply without questioning the attacker. The attacker pretends to be a superior with enough power that the target will comply right away without question.
- Urgency - To create a sense of urgency, an attacker fabricates a scenario of distress to convince an individual that action is immediately necessary.
- Scarcity - Scarcity appeals to the target's greed. If something is in short supply and will not be available, the target is more likely to fall for it.

q_social_engr_tqs_brand_impersonation_secp8

What social engineering technique involves the threat actor committing resources to accurately duplicate a company's logos, formatting, and communication style to make a phishing message or fake website visually compelling and convincing?

Answers:

- ***Brand impersonation**
- Pharming
- Vishing
- Spear phishing

Explanation:

Brand impersonation is a social engineering technique where the threat actor makes a significant effort to create a phishing message or a fake website that accurately duplicates a legitimate company's logos, formatting, and communication style. This level of detail makes the phishing attempt visually compelling and convincing to trick the target into believing it's legitimate.

Pharming involves redirecting users from legitimate websites to malicious ones by corrupting the victim's computer's name resolution process.

Vishing is a type of phishing attack conducted through a voice channel. It is not explicitly related to duplicating a company's branding to create a visually compelling phishing message.

Spear phishing is a highly targeted social engineering attack focusing on a specific individual within the company.

q_social_engr_tqs_business_email_secp8

The senior manager at CyberCorp receives an email from what appears to be a trusted colleague within the company. The email requests sensitive financial information to complete an urgent transaction and looks legitimate, displaying the colleague's name, company logo, and formatting.

What type of sophisticated phishing attack occurs in this scenario?

Answers:

- ***Business email compromise**
- Mass mailer phishing
- Angler phishing
- Whaling

Explanation:

Business email compromise (BEC) is a sophisticated attack that targets specific individuals, such as executives. The threat actor impersonates a trusted colleague, business partner, or vendor to trick the target into performing actions or disclosing information.

Mass mailer phishing is a traditional form of phishing where many emails sent to a broad audience deceive targets into clicking on spoofed links or downloading malware.

Angler phishing involves using social media as the vector to deceive targets into clicking on malicious links or disclosing information.

Whaling is a phishing attack that targets high-level executives or decision-makers in an organization. It is like business email compromise but may not involve posing as a colleague or business partner.

q_social_engr_tqs_deep_fake_secp8

Which of the following is the term used for creating media that looks and or sounds like someone making statements that the person did not make?

Answers:

- ***Deep fake**
- Impersonation
- Brand impersonation
- Disinformation

Explanation:

Deep fakes create media that looks and or sounds like someone making statements that the person did not make or doing something in a picture or video that did not happen.

Impersonation involves an attacker posing as someone with a legitimate need for information. For example, someone might pose as your banker and contacts you to tell you that you are a victim of identity theft, and she will be glad to help you reset your account password. Here the attacker is impersonating your banker and she is contacting you on the pretext of identity theft.

Brand impersonation occurs when attackers create fake websites, emails, or social media profiles that mimic a legitimate brand's online presence. These fake assets are used to deceive individuals into providing personal information or credentials.

Disinformation is the intentional presentation of false information with the intent to influence decisions and actions. Disinformation can be the result of:

- Removing important facts.
- Removing contextual information from articles, statements, videos, or photos.

q_social_engr_tqs_duplicate_logos_secp8

Which disinformation/misinformation tactics create convincing brand impersonation for phishing attacks or pharming websites? (Select two.)

Answers:

- ***By accurately duplicating a company's logos and formatting, such as fonts, colors, and styles, to make the fake site visually compelling.**
- ***By mimicking the style or tone of email communications or website copy to create a convincing fake.**
- Using disinformation to purposefully deceive individuals by spreading false claims and rumors with the intention of causing confusion and harm.
- Repeating false claims or rumors without the intention to deceive others but aiming to get those false facts amplified by others.
- Primarily focusing on providing support for IT resources such as networks, security, or web infrastructure.

Explanation:

A disinformation/misinformation campaign utilizes accurate duplications of a company's logos and formatting to appear more legitimate.

Using the mimicry of communication styles creates convincing brand impersonation. This mimicry can lead to successful phishing attacks or pharming websites that appear visually compelling and authentic.

While disinformation campaigns aim to purposely deceive individuals with false claims, it does not directly relate to brand impersonation or the creation of visually compelling fake messages or websites.

Repeating rumors, false claims, or misinformation does not address brand impersonation or the use of realistic content to boost search rankings for fake websites.

MSPs primarily focus on providing support for IT resources such as networks, security, or web infrastructure.

q_social_engr_tqs_impersonation_01_secp8

Impersonation is a social engineering attack that involves which of the following?

Answers:

- ***Pretending to be someone else and may use persuasive or coercive approaches to manipulate the target.**
- Manipulating the Domain Name System (DNS) to redirect website traffic.
- Sending deceptive emails to trick users into revealing sensitive information.
- Using malware to compromise a network and steal data.

Explanation:

Impersonation is a social engineering attack where the threat actor pretends to be a legitimate user or entity to gain unauthorized access, deceive others, or carry out fraudulent activities.

This option describes a pharming attack, not impersonation. Pharming manipulates Domain Name System (DNS) settings to redirect users to fraudulent websites.

This option refers to a phishing attack, not impersonation. Phishing uses deceptive emails to trick users into revealing sensitive information.

Unrelated to impersonation, this option describes a cyber attack involving malware. Malware attacks aim to compromise networks and steal data, not imitate legitimate users or entities.

q_social_engr_tqs_impersonation_02_secp8

Which social engineering technique involves pretending to be someone else and may use persuasive or coercive approaches to manipulate the target?

Answers:

- ***Impersonation**
- Pharming
- Phishing
- Watering hole attack

Explanation:

Impersonation involves pretending to be someone else and may use persuasive or coercive approaches to deceive the target.

Pharming is an attack that redirects users from a legitimate website to a malicious one but does not actually involve impersonation.

Phishing is a combination of social engineering and spoofing, aiming to trick the target into interacting with a malicious resource, but it doesn't necessarily involve impersonation.

A watering hole attack targets a group of users by compromising a third-party website they may commonly visit, but it is not related to impersonation.

q_social_engr_tqs_impersonation_03_secp8

A social engineer intercepted an end-user's phone call to an internet service provider (ISP) about a home internet outage.

Pretending to be the caller reporting the outage, the attacker immediately contacted the ISP to cancel the service call, dressed up as an internet tech, and then proceeded to enter the end-user's home with permission.

What social engineering attack did the ISP and end-user fall victim to?

Answers:

- ***Impersonation**
- Hoax
- Pharming
- Tailgating

Explanation:

Impersonation is a social engineering attack in which the attacker pretends to be someone else.

In a hoax attack, an email alert or web pop-up will claim to have identified a security problem, such as a virus infection, and offer a tool to fix the problem. The tool, of course, will be some sort of Trojan application.

Pharming relies on corrupting how the victim's computer performs internet name resolution to redirect them from the genuine site to the malicious one.

Tailgating is entering a secure area without authorization by following close behind the person with permission to open the door or checkpoint.

q_social_engr_tqs_phishing_01_secp8

Which of the following attacks tricks victims into providing confidential information (such as identity information or logon credentials) through emails or websites that impersonate an online entity that the victim trusts?

Answers:

- Pharming
- Pretexting
- ***Phishing**
- Preloading

Explanation:

Phishing tricks victims into providing confidential information, such as identity information or logon credentials, through emails or websites that impersonate an online entity that the victim trusts. These entities could include a financial institution or well known e-commerce site. Phishing is a specific form of social engineering.

Pharming involves the attacker executing malicious programs on the target's computer so that any URL traffic redirects to the attacker's malicious website.

Pretexting is conducting research and information gathering to create convincing identities, stories, and scenarios to be used on selected targets.

Preloading is used to set up a target by influencing the target's thoughts, opinions, and emotions.

q_social_engr_tqs_phishing_02_secp8

Customers receive a seemingly genuine email from their trusted bank informing them that their passwords need updating. However, when authenticating, an attacker captures the customer's credentials.

What kind of attack did the bank customers experience?

Answers:

- ***Phishing**
- Vishing
- SMiShing
- Whaling

Explanation:

Phishing is a combination of social engineering and spoofing, where the attacker sets up a spoof website to imitate a trusted one. The attacker then emails users of the genuine website, informing them that their accounts need updating and supplying a disguised link that leads to their spoofed site. Users then authenticate with the spoofed site, capturing their login credentials.

Vishing describes a phishing attack conducted through a voice channel (telephone or Voice over Internet Protocol, also called VoIP, for instance).

Smishing refers to fraudulent SMS texts. Other vectors could include instant messaging or social media sites.

A spear-phishing attack directed specifically against upper levels of management in the organization is sometimes called whaling.

q_social_engr_tqs_phishing_03_secp8

An employee receives an email from an unknown sender claiming to be from the IT department.

The email states that there is a login issue on the network and that the user needs to run the file to resolve the problem. The executable file prompts the user to input a network password, which the threat actor records.

What social engineering technique is the threat actor using in this scenario?

Answers:

- ***Phishing**
- Vishing
- Tailgating
- Pharming

Explanation:

Phishing aims to elicit information or get a target to perform specific actions. The threat actor attempts to deceive the user by sending a fake executable file via email and persuading them to input their network password.

Vishing is a type of social engineering attack conducted via voice channels. There is no indication of voice communication in the scenario.

Tailgating is a physical security attack where an unauthorized person accesses a restricted area by following an authorized person through a secure access point.

Pharming involves redirecting users to a fake website and hijacking the Domain Name System (DNS). There is no indication of pharming since the employee received an email with an executable file to obtain a password.

q_social_engr_tqs_pretexting_01_secp8

What social engineering technique occurs when a threat actor assumes the identity of a remote sales representative and contacts the help desk to urgently or authoritatively obtain login credentials for remote access?

Answers:

- ***Pretexting**
- Phishing
- Watering hole attack

- Brand impersonation

Explanation:

Pretexting is a social engineering tactic where a threat actor deceives a target into sharing sensitive information.

Phishing involves sending deceptive emails with disguised links to trick users into interacting with a spoofed website. However, it does not explicitly include posing as a sales representative or contacting the help desk.

A watering hole attack infiltrates a commonly used third-party website to infect devices without posing as a sales agent or contacting support.

Brand impersonation is copying a company's logos and format to create a convincing phishing message or website. It doesn't involve pretending to be a representative or contacting the help desk.

q_social_engr_tqs_pretexting_02_secp8

The cybersecurity manager of a large organization is investigating a recent security breach that occurred during office hours. Investigatory research shows that the suspect convinced the janitor to let them inside the building because they had forgotten their badge at home.

Once inside, the suspect pulled the fire alarm and accessed the building's network room amongst the chaos. The intruder then attached a monitoring device to a network port before escaping unnoticed.

Which of the following is the social engineering technique the threat actor employed in this scenario?

Answers:

- ***Pretexting**
- Vishing
- Impersonation
- Pharming

Explanation:

The threat actor used pretexting as a social engineering technique. They triggered a fire alarm to create a distraction and a convincing pretext to gain physical access to the network room, attaching a monitoring device to a network port.

Vishing is a phishing attack conducted through a voice channel (telephone or VoIP). There is no involvement of voice communication in this scenario, just a physical intrusion.

Impersonation with persuasive techniques involves convincing the target that the request is natural and without refusal. In this scenario, there is no indication of the threat actor persuading someone to act.

Pharming is a technique that redirects users from a legitimate website to a malicious one. It is irrelevant to this physical intrusion scenario.

q_social_engr_tqs_smishing_secp8

A text message purporting to be from a user's bank requests the recipient to click on a link to verify a recent transaction and provide security details.

What BEST describes the type of attack used?

Answers:

- ***SMiShing**
- Vishing
- Phishing
- Watering hole attack

Explanation:

SMiShing is a social engineering attack that uses text messages to trick people into sharing sensitive information.

Vishing is a type of phishing attack conducted through a voice channel (telephone or VoIP). The scenario explicitly describes a text message-based attack, not a voice phishing phone call.

Phishing is a social engineering technique that tricks the target into interacting with a malicious resource disguised as a trusted one, often using email as the vector. Similarly, the scenario involves a text message rather than an email.

A watering hole attack is a social engineering attack where the threat actor targets a specific group by compromising a website or online platform frequently visited by the target group.

q_social_engr_tqs_social_engineering_secp8

A threat actor poses as a remote sales representative and contacts the help desk of CloudSecure. The threat actor claims to need assistance setting up remote access.

Through a series of convincing phone calls, the threat actor obtains the name and address of the remote access server and a login credential.

What type of attack does this scenario illustrate?

Answers:

- ***Social engineering**
- Phishing
- Man-in-the-middle
- Denial-of-service

Explanation:

The stated scenario illustrates a social engineering attack where the threat actor deceives the help desk into providing sensitive information through several persuasive phone calls.

Phishing attacks involve tricking users into revealing sensitive information through email or messages, but the stated scenario focuses on several deceptive phone calls.

A man-in-the-middle attack intercepts and relays communication, which is not present in the stated scenario. The attack relies on social engineering tactics instead.

A denial-of-service attack will typically cause service disruptions. The stated scenario does not mention anything about service disruptions.

q_social_engr_tqs_typosquatting_01_secp8

An employee at a crypto security company receives an email that appears to be internal to the IT department. The email informs the employee to update the login credentials immediately to prevent account suspension.

The "From" field in the email displays "it_support@cryptosecure.com." However, upon closer inspection, the employee notices the slightly misspelled domain name as "crypt0secure.com."

What technique is the threat actor using in this phishing attempt? (Select two.)

Answers:

- ***Typosquatting**
- ***Spoofing**
- Pharming
- Brand impersonation
- Pretexting

Explanation:

The threat actor is using typosquatting by registering a domain name that is like a legitimate one, hoping users will not notice the difference and assume they are receiving emails from a known source.

The scenario also involves spoofing by impersonating a trusted source, deceiving the target. The company's spoofed email address makes it appear that the email is from the IT department.

Pharming involves redirecting users to a fake website and hijacking the Domain Name System (DNS). There is no pharming since the email has a deceptive domain name and no redirection.

Brand impersonation is committing resources to accurately duplicate a company's logos and formatting to make a phishing message or pharming website a visually compelling fake.

Pretexting is a social engineering tactic where a threat actor deceives a target into sharing sensitive information, and does not directly apply to this particular scenario.

q_social_engr_tqs_typosquatting_02_secp8

Employees at CloudCom receive a suspicious email claiming to be from "CloudCom Support," informing employees that their passwords need to be reset urgently due to a security breach. The email includes a link to a login page that looks identical to CloudCom's official site.

What type of social engineering attack does this scenario exemplify?

Answers:

- ***Typosquatting**
- Phishing
- SMiShing
- Watering hole attack

Explanation:

Typosquatting registers domains like legitimate ones, making users believe they're accessing a trusted site. The attacker creates a hijacked subdomain using the primary domain of a trusted cloud provider. Employees may fall victim to this attack if they overlook minor differences.

The attack uses a deceptive email and fraudulent login page, focusing on typosquatting. Phishing involves email or text-based attacks that trick the target into interacting with a malicious resource disguised as trusted.

While SMiShing involves phishing attacks using SMS texts, the scenario explicitly describes an email-based attack, not a text message.

A watering hole attack targets a specific group by compromising a website visited by the target group. In this scenario, there is no indication of a compromised website.

q_social_engr_tqs_vishing_01_secp8

What is the term for a phishing attack conducted through a voice channel, such as a phone call?

Answers:

- ***Vishing**
- Phishing
- SMiShing
- Pharming

Explanation:

Vishing refers to a phishing attack conducted through a voice channel, typically over the phone or VoIP, where the threat actor persuades the target to reveal sensitive information.

Phishing is a social engineering technique that tricks the target into interacting with a malicious resource disguised as a trusted one, often using email as the vector.

SMiShing stands for ""SMS Phishing,"" which involves sending deceptive text messages (SMS) to trick the recipient into interacting with a malicious resource or providing sensitive information.

Pharming is a technique that redirects users from a legitimate website to a malicious one; unrelated to voice channels.

q_social_engr_tqs_vishing_02_secp8

Which of the following social engineering attacks uses voice over IP (VoIP) to gain sensitive information?

Answers:

- ***Vishing**
- Spear phishing
- Shoulder surfing
- Hoax

Explanation:

Vishing is a social engineering attack that uses voice over IP (VoIP) to gain sensitive information. The term is a combination of voice and phishing.

Shoulder surfing involves looking over someone's shoulder while that person works on a computer or reviews documents.

In spear phishing, attackers gather information about the victim, such as identifying which online banks they use. They then send phishing emails for that specific bank.

Email hoaxes are often easy to spot because of the bad spelling and terrible grammar.

q_social_engr_tqs_vishing_03_secp8

A representative at a company reports receiving numerous unsolicited phone calls seeking banking information for a credit report.

Which social engineering variant is the finance director experiencing?

Answers:

- ***Vishing**
- Spear phishing
- Whaling
- SMiShing

Explanation:

Vishing is a type of phishing attack conducted through a voice channel (telephone or Voice over Internet Protocol, for instance) such as someone purporting to represent the bank or another official institution calling targets.

Spear phishing is a phishing scam where the attacker has some information that is more likely to fool an individual target by the attack.

Whaling is a type of spear phishing attack explicitly directed against the upper levels of management in an organization.

SMiShing is an attack that refers to using simple message service (SMS) text communications as the vector.

q_social_engr_tqs_voice_secp8

Vishing is a type of phishing attack that uses which kind of vector?

Answers:

- ***Voice or telephone**
- SMiShing
- Pharming
- Spear phishing

Explanation:

Vishing attacks are a social engineering tactic that uses the voice or a telephone network to deceive victims and gather sensitive information.

SMiShing is a type of phishing attack that uses simple message service (SMS) text communications as the vector.

Vishing attacks are voice-based, while pharming attacks manipulate Domain Name System (DNS) settings to redirect website traffic to fraudulent websites, making them unrelated in their methods and targets.

Spear phishing is not a type of vector but a highly targeted social engineering attack focusing on a specific individual within a company.

q_social_engr_tqs_watering_hole_01_secp8

Which of the following is a passive computer attack technique in which an attacker anticipates or observes the websites an organization uses often and infects them with malware?

Answers:

- ***Watering hole**
- Pretexting
- Social networking
- Typosquatting

Explanation:

A watering hole is a passive computer attack technique in which an attacker anticipates or observes the websites an organization uses often and infects them with malware. Members of the targeted group can then become infected.

Pretexting is using a fictitious scenario to persuade someone to perform an action or give information they aren't authorized to share.

Social networking involves using social media platforms to steal identities and information. Also, many attackers use social media to scam users. These scams are designed to entice the user to click a link that brings up a malicious site the attacker controls. Usually, the site requests personal information and sensitive data, such as an email address or credit card number.

Typo squatting, also called URL hijacking, relies on mistakes, such as typos made by users inputting a website address into a web browser. When a user enters an incorrect website address, the squatter may lead them to any URL.

q_social_engr_tqs_watering_hole_02_secp8

Which of the following is an example of a watering hole attack?

Answers:

- ***Targeting a group of individuals who frequent an unsecured third-party website to compromise their computers to gain access.**
- Sending deceptive emails to trick users into clicking on malicious links.
- Exploiting weak login credentials to gain unauthorized network access.
- Installing malicious software through a fake antivirus program.

Explanation:

Injecting malware into a popular website that a specific user group frequently visits is an example of a watering hole attack. The attack leverages users' trust in the site to compromise their devices.

Sending deceptive emails is a phishing attack, not a watering hole attack, where victims, lured through deceptive emails, interact with malicious content.

Exploiting login credentials is a network breach through weak credentials, not a watering hole attack, which typically involves compromising a website rather than the network.

Installing malicious software describes malware installation through a fake antivirus program, not a watering hole attack targeting specific websites, not software downloads.

q_social_engr_tqs_watering_hole_03_secp8

What social engineering attack relies on targeting individuals who frequent an unsecured third-party website to compromise their computers and gain access to a specific organization's systems?

Answers:

- ***Watering hole**
- Pharming
- Spear phishing
- Impersonation

Explanation:

A watering hole attack is a social engineering technique where the attacker identifies a popular and frequently visited website used by the target group and compromises that website with exploit code. Their computers become infected when target group members visit the website, and the attacker can then use this foothold to penetrate the organization's systems.

Pharming involves redirecting users from legitimate websites to malicious ones by corrupting the victim's computer's name resolution process. It is not specific to targeting a group of individuals.

Spear phishing is a highly targeted social engineering attack focusing on a specific individual within a company.

Impersonation involves pretending to be someone else to deceive the target.

q_social_engr_tqs_whaling_secp8

An attack that targets senior executives and high-profile victims is referred to as what?

Answers:

- ***Whaling**
- Vishing
- Pharming
- Scrubbing

Explanation:

Whaling is another form of phishing that targets senior executives and high-profile victims.

Pharming involves the attacker executing malicious programs on the target's computer so that when the user enters any URL, it redirects traffic to the attacker's malicious website.

Vishing is like phishing, but instead of an email, the attacker uses voice over IP (VoIP) to gain sensitive information. The term is a combination of voice and phishing.

Scrubbing is one of the most common ways to pick a lock.

2.3 Malware

As you study this section, answer the following questions:

- What is the difference between a virus and a worm?
- Which types of malware typically use email to spread?
- What does it mean for software to be quarantined?
- Why is it a good practice to show file extensions?
- What must you do to ensure that you are protected from the latest virus variations?

In this section, you will learn to:

- Implement malware protections.
- Use Windows security.
- Configure Windows Defender protections to secure a network from malware.

Key terms for this section include the following:

Term	Definition
Malware	Software that serves a malicious purpose, typically installed without the user's consent (or knowledge).
Trojan	A malicious software program hidden within an innocuous-seeming piece of software. Usually, the Trojan is used to try to compromise the security of the target computer.
Potentially unwanted programs (PUPs)/potentially unwanted applications (PUAs)	Software that cannot definitively be classed as malicious, but may not have been chosen or wanted by the user.
Virus	Malicious code inserted into an executable file image. The malicious code is executed when the file is run and can deliver a payload, such as attempting to infect other files.
Malicious process	A process executed without proper authorization from the system owner for the purpose of damaging or compromising the system.
Worm	A type of malware that replicates between processes in system memory and can spread over client/server network connections.
Shellcode	A lightweight block of malicious code that exploits a software vulnerability to gain initial access to a victim system.

Advanced persistent threat (APT)	An attacker's ability to obtain, maintain, and diversify access to network systems using exploits and malware.
Adware	Software that records information about a PC and its user. Adware is used to describe software that the user has acknowledged can record information about their habits.
Spyware	Software that records information about a PC and its users, often installed without the user's consent.
Keylogger	Malicious software or hardware that can record user keystrokes.
Backdoor	A mechanism for gaining access to a computer that bypasses or subverts the normal method of authentication.
Remote access Trojan (RAT)	Malware that creates a backdoor remote administration channel to allow a threat actor to access and control the infected host.
Botnet	A group of hosts or devices that has been infected by a control program called a bot, which enables attackers to exploit the hosts to mount attacks.
Command and control (C2 or C&C)	Infrastructure of hosts and services with which attackers direct, distribute, and control malware over botnets.
Covert channel	A type of attack that subverts network security systems and policies to transfer data without authorization or detection.
Internet Relay Chat (IRC)	A group communications protocol that enables users to chat, send private messages, and share files.
Rootkit	Class of malware that modifies system files, often at the kernel level, to conceal its presence.
Ransomware	Malware that tries to extort money from the victim by blocking normal operation of a computer and/or encrypting the victim’s files and demanding payment.
Crypto-mining	Malware that hijacks computer resources to create cryptocurrency.

Logic bomb	A malicious program or script that is set to run under particular circumstances or in response to a defined event.

This section helps you prepare for the following certification exam objectives:

Exam	Objective

CompTIA Security+ SY0-701	2.4 Given a scenario, analyze indicators of malicious activity.
	• Malware attacks
	  ○ Ransomware
	  ○ Trojan
	  ○ Worm
	  ○ Spyware
	  ○ Bloatware
	  ○ Virus

TestOut Security Pro	3.1 Harden computer systems 3.1.2 Configure anti-virus protection

2.3.1 Malware (Lesson Video)

Transcript:

Malware is software designed to infiltrate or damage a computer system without the owner's consent or knowledge. It often attempts to hide itself. And some malware even takes control of the computer system.

There's a long list of malware types. I'm going to tell you about just a few of them.
First, let me introduce you to worms. A worm propagates without a file. It travels across computer networks without any user assistance, and it automatically replicates itself. Worms are one of the deadliest malware types because they can quickly spread to millions of computers. They usually take advantage of unpatched vulnerabilities in computer systems. To avoid a worm infection, keep your systems patched.
Next, there's the Trojan. The Trojan virus is named after the Trojan horse in Greek mythology. It seems benign, but it's not. It usually comes in the form of a useful application hiding malicious code. It may be explicit or run invisibly. Trojans don't self-replicate like worms, and they aren't attached to a file like a virus. But they can create back doors for an attacker, allowing remote control of the infected machine.
The Remote Access Trojan, or RAT, is a common virus. A RAT is designed to give the attacker remote desktop access, including a GUI. It gives the hacker complete control over the system and allows them to view all communications, webcam footage, files, and emails.
Since a RAT requires the hacker to connect to the user through a port that isn't commonly used for internet access, if the user is behind a firewall, this often prevents the hacker from connecting. If the hacker can get around the firewall and open that port, then they're able connect.
Next, there are rootkits. This malicious software hides in the system and alters the system's processes and registry entries. A rootkit is almost invisible. It resides below antivirus software detection. This makes it difficult to detect and very dangerous. Special Anti-rootkit software can help detect rootkits.

Let's move on to the logic bomb. This is a piece of malicious code designed to execute only under pre-defined conditions. It'll lay dormant until the pre-defined condition is met, such as a certain time or date. Logic bombs can range from benign, such as pranks, to dangerous, such as driver formatters. One example is a piece of code that lies dormant until it executes once per year, perhaps on someone's birthday. Another example is a user opening a certain program that activates it, deleting the contents of disk drives.
Next is spyware. This is computer software installed without the user's consent or knowledge. It's designed to intercept data or take partial control of the user's computer. Spyware often collects personal information about the user, like internet surfing habits and passwords. It uses tracking cookies to collect information about the user's activities and report it to the hacker. It can also interfere with a user's control in other ways, such as installing additional software, changing computer settings, and redirecting web browsers.
An important malware to know is ransomware. It allows a hacker to gain access to a system, plant a virus that encrypts all user data, and then demand a payment for decrypting the data. If the victim doesn't pay, the hacker threatens to destroy the data. But there's no guarantee that the hacker will actually send the decryption key once the victim's paid for it. There's also no guarantee that the victim will pay the ransom. If they have a backup still intact, they may choose not to pay.
Because of this, ransomware is becoming less prevalent and cryptomalware is gaining popularity. The difference between ransomware and cryptomalware is that crypto operates quietly in the background and keeps going indefinitely until it's noticed. This is called cryptomining. Mining cryptocurrency wears down a system substantially. It eats up bandwidth and processing power, which slows the system down and affects productivity. If it goes on long enough it can even cause graphic cards to die, processors to burn out, and memory to act unpredictably.
Another interesting malware is the fileless virus. It uses legitimate programs to infect a computer. Because it doesn't rely on files, it leaves no footprint, making it undetectable by most antivirus, whitelisting, and other traditional endpoint security solutions. Fileless malware isn't a traditional virus, but it works in a similar way by operating in memory. It never even touches the hard drive. Many hackers use social engineering to get users to click on a link in a phishing email. When the web page opens, the virus gets into the inner recesses of a trusted application such as PowerShell or Windows script host executables.
Now let's talk about how you can prevent falling victim to malicious software. First, use the latest version and patch level for your web browser. Then install the latest patches for your operating system. You should also install antivirus, anti-spyware, anti-rootkit, and personal firewall software. On all anti-malware software, be sure to keep your definitions up to date for the latest threats. Use a pop-up blocker to prevent adware. Use software to control cookies on your system. Schedule regular scans to constantly detect malware.
If a scan does detect malware, quarantine or delete the malicious software. Malware may cause permanent damage to the system. Even though anti-malware software can scan, detect, and delete malware for you, the system may still need repairs. You might have to reinstall applications or even reinstall the entire operating system.
Many companies image their operating systems, so if malware is detected, they'll simply send down a brand new image that overrides the entire operating system.
All right, that's it for this lesson. In this video, we talked about different types of malware and how they work. We also learned how to prevent and repair malware in case your system or network becomes infected.

2.3.2 Malware Facts

By classifying the various types of malware and identifying the signs of infection, security teams are better prepared to remediate compromised systems or prevent malware from executing in the first place.

This lesson covers the following topics:

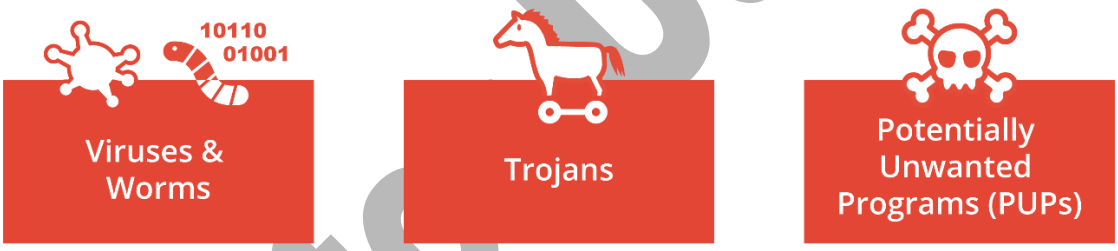
- Malware classification
- Computer viruses
- Spyware and Keyloggers
- Backdoors and Remote Access Trojans
- Rootkits
- Ransomware, Crypto-Malware, and Logic Bombs
- Crypto-Ransomware
- Logic Bombs

Malware Classification

Many of the intrusion attempts perpetrated against computer networks depend on the use of malicious software or malware. Malware is simply defined as software that does something bad from the perspective of the system owner. A complicating factor with malware classification is the degree to which its installation is expected or tolerated by the user.

Some malware classifications, such as Trojan, virus, and worm, focus on the vector used by the malware. The vector is the method by which the malware executes on a computer and potentially spreads to other network hosts. The following categories describe some types of malware according to vector:

- **Viruses and worms** represent some of the first types of malware and spread without any authorization from the user by being concealed within the executable code of another process. These processes are described as being infected with malware.
- **Trojan** refers to malware concealed within an installer package for software that appears to be legitimate. This type of malware does not seek any type of consent for installation and is actively designed to operate secretly.
- **Potentially unwanted programs (PUPs)/Potentially unwanted applications (PUAs)** are software installed alongside a package selected by the user or perhaps bundled with a new computer system. Unlike a Trojan, the presence of a PUP is not automatically regarded as malicious. It may have been installed without active consent or with consent from a purposefully confusing license agreement. This type of software is sometimes described as *grayware* rather than malware. It can also be referred to as bloatware.



Malware classification by vector.

Other classifications are based on the payload delivered by the malware. The *payload* is an action performed by the malware other than simply replicating or persisting on a host. Examples of payload classifications include spyware, rootkit, remote access Trojan (RAT), and ransomware.

Computer Viruses

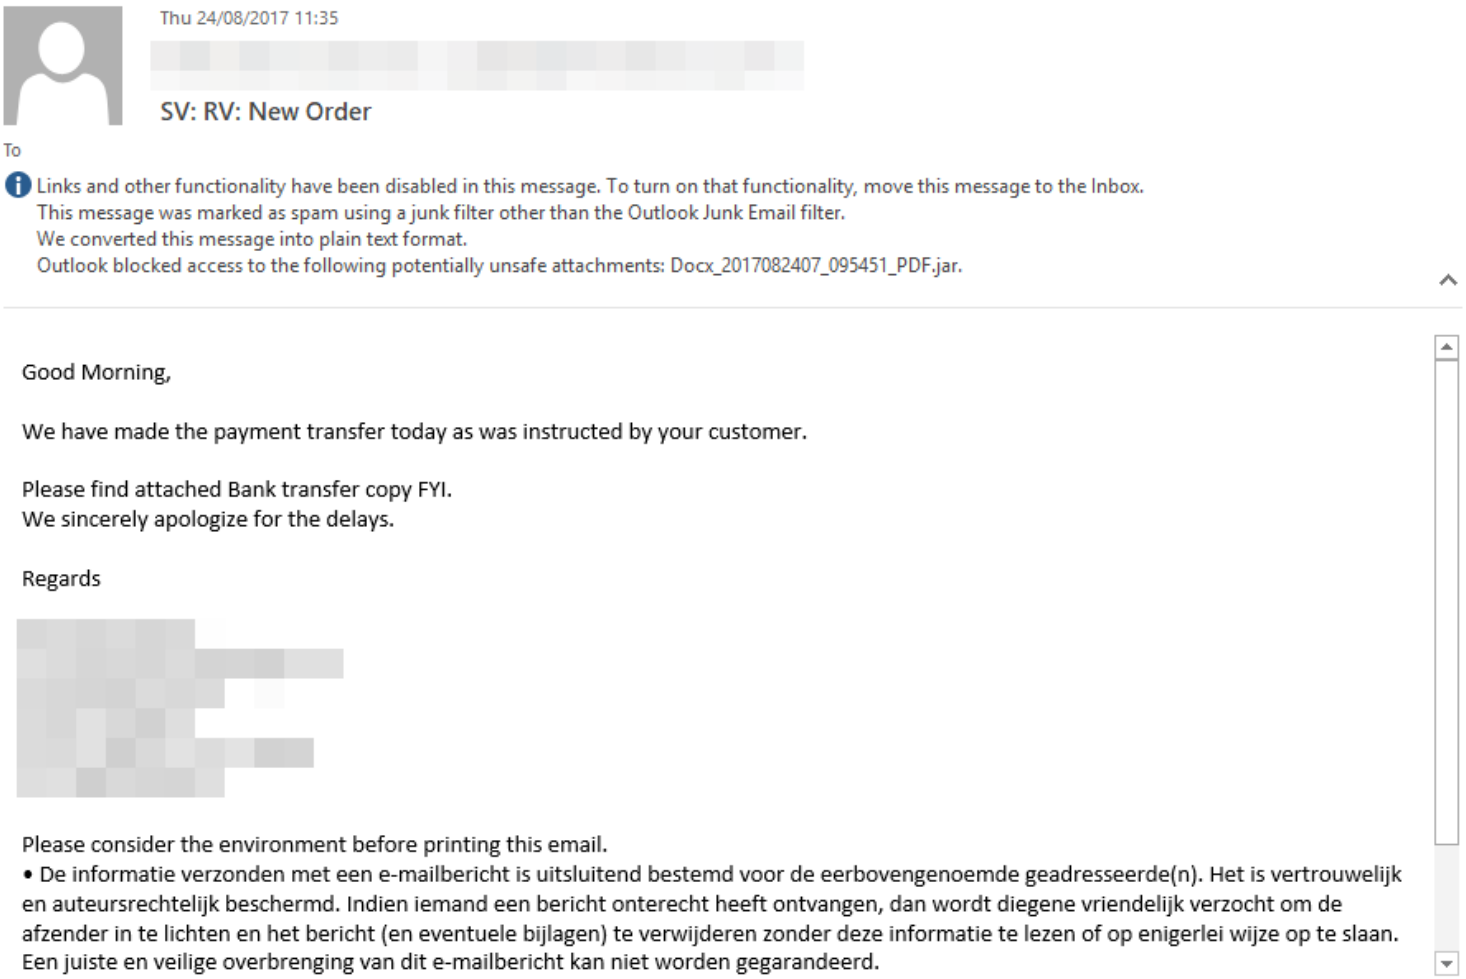
A computer virus is a type of malware designed to replicate and spread from computer to computer, usually by "infecting" executable applications or program code. There are several different types of viruses, and they are generally classified by the different types of file or media that they infect:

- **Non-resident/file infector** — the virus is contained within a host executable file and runs with the host process. The virus will try to infect other process images on persistent storage and perform other payload actions. It then passes control back to the host program.
- **Memory resident** — when the host file is executed, the virus creates a new process for itself in memory. The malicious process remains in memory, even if the host process is terminated.
- **Boot** — the virus code is written to the disk boot sector or the partition table of a fixed disk or USB media and executes as a memory-resident process when the OS starts, or the media is attached to the computer.
- **Script and macro viruses** — the malware uses the programming features available in local scripting engines for the OS and/or browser, such as PowerShell, Windows Management Instrumentation (WMI),

JavaScript, Microsoft Office documents with Visual Basic for Applications (VBA) code enabled, or PDF documents with JavaScript enabled.

In addition, the term "multipartite" is used for viruses that use multiple vectors, and the term "polymorphic" is used for viruses that can dynamically change or obfuscate their code to evade detection.

What these types of viruses have in common is that they must infect a host file or media. An infected file can be distributed through any normal means—on a disk, on a network, as an attachment to an email or social media post, or as a download from a website.



Unsafe attachment detected by Outlook's mail filter—The "double" file extension is an unsophisticated attempt to fool any user not already alerted by the use of both English and German in the message text. (Screenshot used with permission from Microsoft.)

A computer worm is memory-resident malware that can run without user intervention and replicate over network resources. A virus is executed only when the user performs an action such as downloading and running an infected executable process, attaching an infected USB stick, or opening an infected document with macros or scripting enabled. By contrast, a worm can execute by exploiting a vulnerability in a process when the user browses a website, runs a vulnerable server application, or is connected to an infected file share. For example, the Code Red worm was able to infect early versions of Microsoft's IIS web server software via a buffer overflow vulnerability. It then scanned randomly generated IP ranges to try and infect other vulnerable IIS servers.

The primary effect of the first type of computer worm is to rapidly consume network bandwidth as the worm replicates. A worm may also be able to crash an operating system or server application, performing a denial of service attack. Also, like viruses, worms can carry a payload that can be written to perform any type of malicious action.

The Conficker worm illustrated the potential for remote code execution and memory-resident malware to effect highly potent attacks. As malware has continued to be developed for criminal intent and security software became better able to detect and block static threats, malware code and techniques have become more sophisticated. The term "fileless" has gained prominence to refer to these modern types of malware. Fileless is not a definitive classification, but it describes a collection of common behaviors and techniques:

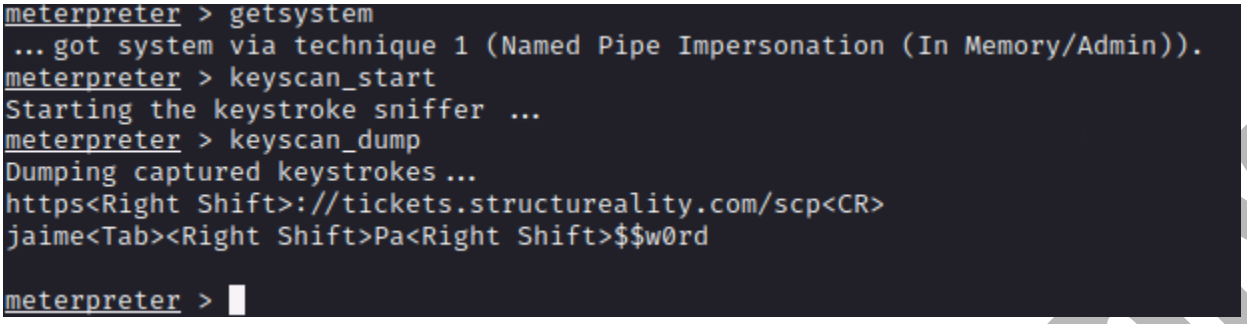
- Fileless malware does not write its code to disk. The malware uses memory-resident techniques to run in its own process, within a host process or dynamic link library (DLL), or a scripting host. This does not mean that there is no disk activity at all, however. The malware may change registry values to achieve persistence (executing if the host computer is restarted). The initial execution of the malware may also depend on the user running a downloaded script, file attachment, or Trojan software package.
- Fileless malware uses lightweight shellcode to achieve a backdoor mechanism on the host. The shellcode is easy to recompile in an obfuscated form to evade detection by scanners. It is then able to download additional packages or payloads to achieve the threat actor's objectives. These packages can also be obfuscated, streamed, and compiled on the fly to evade automated detection.
- Fileless malware may use "live off the land" techniques rather than compiled executables to evade detection. This means that the malware code uses legitimate system scripting tools, notably PowerShell and Windows Management Instrumentation (WMI), to execute payload actions. If they can be executed with sufficient permissions, these environments provide all the tools the attacker needs to perform scanning, reconfigure settings, and exfiltrate data.

The terms " advanced persistent threat (APT) " and "advanced volatile threat (AVT)" can be used to describe this general class of modern fileless/live-off-the-land malware. Another useful classification is a low-observable characteristic (LOC) attack. The exact classification is less important than the realization that adversaries can use any variety of coding tricks to effect intrusions and that their tactics, techniques, and procedures to evade detection are continually evolving.

Spyware and Keyloggers

The first viruses and worms focused on the destructive potential of being able to replicate. As the profitable uses of this software became apparent, however, they started to be coded with payloads designed to facilitate intrusion, fraud, and data theft. Bloatware and malware can be used for different levels of monitoring:

- **Tracking cookies** — a cookie is a plaintext file, not malware, but if permitted by browser settings, third-party cookies can be used to record web activity, track the user's IP address, and harvest various other metadata, such as search queries and information about the browser software and configuration. Tracking cookies are created by adverts and analytics widgets embedded into many websites.
- **Supercookies and beacons** — as browser software gives the user some control over what cookies to accept, web marketing companies have come up with alternative ways to implement tracking that are difficult to disable. A supercookie is a means of storing tracking data in a non-regular way, such as saving it to a cache without declaring the data to be a cookie or encoding data into header requests. A beacon is a single-pixel image embedded into a website. While invisible to the user, the browser must request to download the pixel to load the site, giving the beacon host the opportunity to collect metadata, perform browser fingerprinting, and potentially run tracking scripts.
- **Adware** — this is a class of PUP/bloatware that performs browser reconfigurations, such as allowing tracking cookies, changing default search providers, opening sponsor's pages at startup, adding bookmarks, and so on. Adware may be installed as a program or browser extension/plug-in.
- **Spyware** — this is malware that can perform adware-like tracking but also monitor local application activity, take screenshots, and activate recording devices, such as a microphone or webcam. Another spyware technique is to perform DNS redirection to pharming sites.
- **Keylogger** — this is spyware that actively attempts to steal confidential information by recording keystrokes. The attacker will usually hope to discover passwords or credit card data.



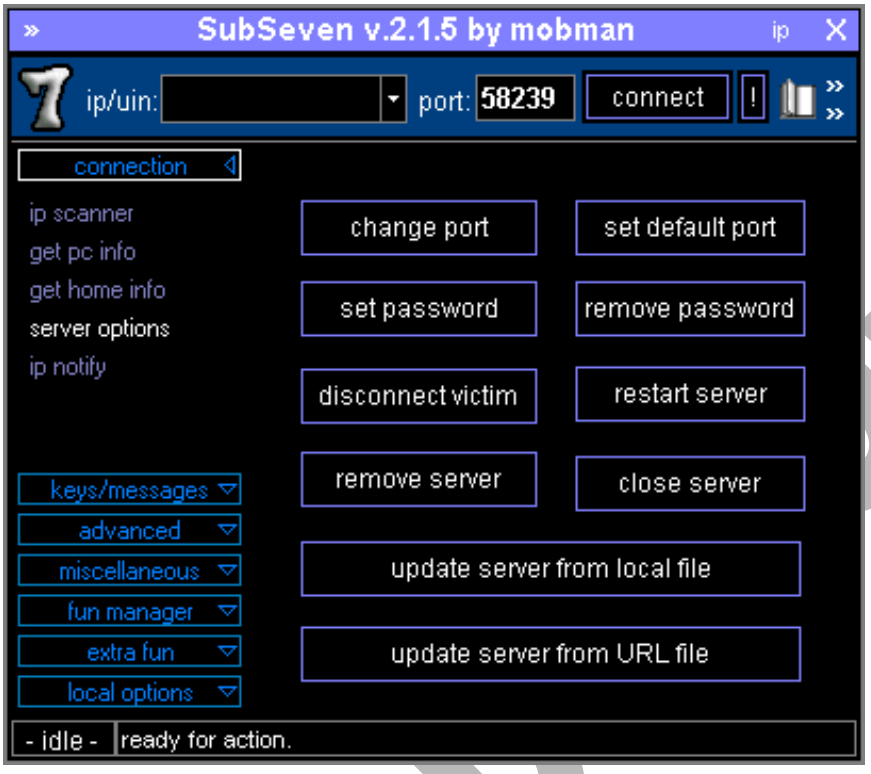
Using the Metasploit Meterpreter remote access tool to dump keystrokes from the victim machine, revealing the password used to access a web app.

Keyloggers are not only implemented as software. A malicious script can transmit key presses to a third-party website. There are also hardware devices to capture key presses to a modified USB adapter inserted between the keyboard and the port. Such devices can store data locally or come with Wi-Fi connectivity to send data to a covert access point. Other attacks include wireless sniffers to record key press data, overlay ATM pin pads, and so on.

Backdoors and Remote Access Trojans

Any type of access method to a host that circumvents the usual authentication method and gives the remote user administrative control can be referred to as a backdoor . A remote access Trojan (RAT) is backdoor malware that mimics the functionality of legitimate remote control programs but is designed specifically to operate covertly. Once the RAT is installed, it allows the threat actor to access the host, upload files, and install software or use "live off the land" techniques to effect further compromises. In this context, RAT can also stand for remote administration tool. A host that is under malicious control is sometimes described as a zombie.

A compromised host can be installed with one or more bots. A bot is an automated script or tool that performs some malicious activity. A group of bots that are all under the control of the same malware instance can be manipulated as a botnet by the herder program. A botnet can be used for many types of malicious purposes, including triggering distributed denial of service (DDoS) attacks, launching spam campaigns, or performing cryptomining.



SubSeven RAT. (Screenshot used with permission from Wikimedia Commons by CCAS4.0 International.)

Whether a backdoor is used as a standalone intrusion mechanism or to manage bots, the threat actor must establish a connection from the compromised host to a command and control (C2 or C&C) host or network. This network connection is usually the best way to identify the presence of a RAT, backdoor, or bot. There are many means of implementing a C&C network as a covert channel to evade detection and filtering. Historically, the Internet Relay Chat (IRC) protocol was popular. Modern methods are more likely to use command sequences embedded in HTTPS or DNS traffic.

Backdoors can be created in other ways than by infection by malware. Programmers may create backdoors in software applications for testing and development that are subsequently not removed when the application is deployed. Backdoors are also created by misconfiguration of software or hardware that allows access to unauthorized users.

Rootkits

In Windows, Trojan malware that depends on manual execution by the logged-on user inherits the privileges of that user account. If the account has only standard permissions, the malware can only add, change, or delete files in the user's profile and run only apps and commands that the user is permitted to.

If the malware attempts to change system-wide files or settings, it requires local administrator-level privileges. To obtain those through manual installation or execution, the user must be confident enough in the Trojan package to confirm the User Account Control (UAC) prompt or enter the credentials for an administrative user.

If the malware gains local administrator-level privileges, there are still protections in Windows to mitigate abuse of these permissions. Critical processes run with a higher level of privilege called SYSTEM. Consequently, Trojans installed or executed with local administrator privileges cannot conceal their presence entirely and will show up as a running process or service. Often, the process image name is configured to resemble a genuine executable or library to avoid detection. For example, a Trojan may use the filename "rund1132.exe" to masquerade as "rundll32.exe." To ensure persistence (running when the computer is restarted), the Trojan may have to use a registry entry or create itself as a service, which can usually be detected easily.

If the malware can be delivered as the payload for an exploit of a severe vulnerability, it may be able to execute without requiring any authorization using SYSTEM privileges. Alternatively, the malware may be able to use an exploit to escalate privileges to SYSTEM level after installation. Malware running with this level of privilege is referred to as a rootkit . The term derives from UNIX/Linux, where any process running as the root superuser account has unrestricted access to everything from the root of the file system down.

In theory, there is nothing about the system that a rootkit could not change. In practice, Windows uses other mechanisms to prevent misuse of kernel processes, such as code signing. Consequently, what a rootkit can do depends largely on adversary capability and level of effort. When dealing with a rootkit, you should be aware that there is the possibility that it can compromise system files and programming interfaces, so that local shell processes, such as Explorer, taskmgr, or tasklist on Windows or ps or top on Linux, plus port scanning tools, such as netstat, no longer reveal its presence (at least, if run from the infected machine). A rootkit may also contain tools for cleaning system logs, further concealing its presence.

Software processes can run in one of several "rings." Ring 0 is the most privileged (it provides direct access to hardware) and should be reserved for kernel processes only. Ring 3 is where user-mode processes run; drivers and I/O processes may run in Ring 1 or Ring 2. This architecture can also be complicated by the use of virtualization.

There are also examples of rootkits that can reside in firmware (either the computer firmware or the firmware of any sort of adapter card, hard drive, removable drive, or peripheral device). These can survive any attempt to remove the rootkit by formatting the drive and reinstalling the OS. For example, the US intelligence agencies have developed DarkMatter and Quark Matter UEFI rootkits targeting the firmware on Apple Macbook laptops.

Ransomware, Crypto-Malware, and Logic Bombs

Ransomware is a type of malware that tries to extort money from the victim by making the victim’s computer and/or data files unavailable and demanding payment. One class of ransomware will display threatening messages, such as requiring Windows to be reactivated or suggesting that the computer has been locked by the police because it was used to view child pornography or for terrorism. This may block access to the file system by installing a different shell program, but this sort of attack is usually relatively simple to fix.

Ransomware uses payment methods, such as wire transfer, cryptocurrency, or premium rate phone lines, to allow the attacker to extort money without revealing their identity or being traced by local law enforcement.

WannaCry ransomware. (Image by Wikimedia Commons.)

Scareware refers to malware that displays alarming messages, often disguised to look like genuine OS alert boxes. Scareware attempts to alarm the user by suggesting that the computer is infected or has been hijacked.

Crypto-Ransomware

The crypto class of ransomware attempts to encrypt data files on any fixed, removable, and network drives. If the attack is successful, the user will be unable to access the files without obtaining the private encryption key, which is held by the attacker. If successful, this sort of attack is extremely difficult to mitigate unless the user has backups of the encrypted files. One example of crypto-ransomware is CryptoLocker, a Trojan that searches for files to encrypt and then prompts the victim to pay a sum of money before a certain countdown time, after which the malware destroys the key that allows the decryption.

Cryptojacking Malware

Another type of crypto-malware hijacks the resources of the host to perform cryptocurrency mining. This is referred to as crypto-mining , and malware that performs crypto-mining maliciously is classed as *cryptojacking* . The total number of coins within a cryptocurrency is limited by the difficulty of performing the calculations necessary to mint a new digital coin. Consequently, new coins can be very valuable, but it takes enormous computing resources to discover them. Cryptojacking is often performed across botnets.

Logic Bombs

Some types of malware do not trigger automatically. Having infected a system, they wait for a preconfigured time or date (time bomb) or a system or user event (logic bomb). Logic bombs also need not be malware code. A typical example is a disgruntled systems administrator who leaves a scripted trap that runs in the event their account is deleted or disabled. Antivirus software is unlikely to detect this kind of malicious script or program. This type of trap is also referred to as a *mine* .

2.3.3 Malware Protection Facts

Malware is software designed to infiltrate or damage a computer system without the owner's consent or knowledge. Some malware attempts to hide itself or can provide a remote attacker control of the computer system.

This lesson covers the following topics:

- Malware prevention
- Malware recovery

Malware Prevention

Regardless of the type of malware, there are some common things you can do to prevent malware infection:

Option	Description
Patches	As corporations find errors, they regularly release them in updates and patches. Ensure that you are at the current version of the following: • Hardware Firmware Updates • Server and Client Operating Systems • Applications, especially your web browser • Malware protection software
Anti-malware	Install antivirus or anti-malware software to protect against known infections. Consider the following: • Choose anti-malware software from a reputable company. Do not let scareware fool you into purchasing a product that may not work or is actually a virus. • Keep definition files up-to-date. • Enable antivirus scanning for email attachments. • Enable scanning of files downloaded from the internet. • Enable antivirus scanning for all removable storage, such as USB flash drives and CD-ROMs. • Schedule regular scans.
Browser Settings	Utilize browser settings to help prevent infection, such as: • Enable a pop-up blocker. • Enable privacy controls. • Monitor and manage cookies. • Regularly clear the cache/history.

Option	Description
	• Disable or configure Autocomplete settings not to store sensitive information.
Firewall	Modern operating systems include a local firewall. This will help protect against unauthorized connections to the local host and attempts by malicious software to make outgoing connections to command and control servers.
Training	Educate end users about common safety tips, such as: • Examine and email attachments for incorrect file extensions and confirm with the sender what they sent if possible. • If pop-ups occur for unknown software, ask to install a new antivirus or more; do not accept and exit the dialog. Then contact IT. • Do not use social media at work where malicious links could cause the work computer to be infected. • Hover over all links to verify that the target URL is valid. • Do not use any devices that they find lying around the office. • Only use reputable software approved by the organization.
Web Filter	If there is a need to have additional control, consider installing a web filter. This provides the ability to block access to malicious sites that users might be visiting regularly.

Malware Recovery

Malware can permanently damage your system. Recovery from malware can include the following steps:

- **Remediate** problems as prompted. *Remediation* is the process of correcting problems. Most antivirus software remediates problems automatically or semi-automatically by prompting you to identify the action to take. Possible actions in response to problems are:
    - **Repair the infection** . Repair is possible for true viruses that have attached themselves to valid files. During the repair, the virus is removed, and the file is placed back in its original state when possible.
    - **Quarantine the file** . Quarantine moves the infected file to a secure folder where it cannot open or run normally. You might quarantine an infected file that cannot be repaired to see if another tool or utility can recover the file at another time.
    - **Delete the file** . You should delete malicious files such as worms, Trojan horse programs, spyware, or adware programs.
    - Periodically review the quarantine folder and delete any files you do not want to recover.
- **Reinstall** applications or features.
- **Re-image** a machine if your organization uses imaging solutions. Re-imaging or installing from scratch is often faster and more effective than malware removal and cleanup. If an image is not available, reinstall the operating system.

2.3.4 Implementing Malware Protections (Demo Video)

Transcript:

In this demonstration, we're going look at the Windows Security app. In previous versions of Windows, this was known as Windows Defender or Windows Defender Security Center. Either way, its functionality as Windows' default anti-

malware software still remains the same. The name of the anti-malware software that's controlled by this app has also been renamed. It's called Microsoft Defender now.

Let's delve into the Windows Security app a little more. Let's come down here, type Security, and click the Windows Security app to open it.

When you start the app up, you'll see Security at a glance. They've divided the whole thing into smaller subsections for easier navigation, like Virus & threat protection, Account protection, Firewall & network protection, and so on. If you look at the bottom-right corner of each category icon, you'll see a green checkmark that indicates that each section is currently providing protection.

If, on the other hand, you see a yellow exclamation point triangle on the icon, that indicates that something might be amiss. And if you see a red X here, it means that something needs your immediate attention.

Okay, let's take a closer look at Virus & threat protection. As I mentioned before, the green checkmark tells us that no action is needed at this moment. But let's click it to take a closer look anyway.

Virus & threat protection is what Windows Defender used to be—it takes a thorough look at your computer system and checks for things that might be concerning. Here, we can look at Current threats, Protection settings, Protection updates, and Ransomware protection.

Under Current threats, we see the last time the system was scanned, how many threats were found, and how many files were scanned as well. By default, Microsoft Defender scans your system on a regular basis. But if you're concerned that some type of malware may have gotten into your system and you don't want to wait until the next scheduled scan, you can manually scan the system whenever you like by clicking Quick scan. You can change Scan options as well.

Notice that you have four options for running a manual scan. The first one is the Quick scan I mentioned, which checks your system in places where threats are commonly found. A Full scan checks every file on the system. The disadvantage of full scans, obviously, is that they take a lot longer. The third option would be to run a Custom scan to check specific files and folders. The last option is a Microsoft Defender Offline scan. This one takes about 15 minutes and restarts the system as part of the routine.

If you run a scan and do find malware, it means that your system is already infected and needs to be remediated. Obviously, it's much better to try to detect malware before it infects your system, say, as you're downloading a file from a malicious website. That's where Real-time protection comes in.

Instead of just scanning for malicious files on your hard disk drives, Real-time protection watches what you're doing and tries to detect malware as it enters the system. To turn on Real-time protection, let's come down here, to Virus & threat protection settings. Notice that it tells us that Real-time protection is currently turned on.

Understand that with this software, there are a few different ways to utilize the protection options. One is to generically scan files for characteristics that might indicate that that file is either malware or contains malware of some sort. There's also Cloud-delivered protection, which sends information to Microsoft that allows them to update their definition files and get them out faster. We'll talk about definition files shortly. You also have the option to send those malware samples to Microsoft directly. You can also use Tamper Protection, which monitors important security features and prevents them from being changed. Controlled folder access allows further protection for dedicated locations and files on your system.

Occasionally, you may need to implement an exclusion. This is any item, file, folder, or process that you want to exclude from being scanned. Take caution when you're adding exclusions, as some excluded items could contain threats that could make your system vulnerable. To add an exclusion, click the Add or remove exclusions link, click the Add an exclusion button, select the type of item to be added, browse to it, and select it.

Now let's go back and look at Virus & threat protection updates. First, it's important to know that Windows Security uses files called definitions to help detect threats and protect your system from them. Windows Defender tries to automatically download the latest definitions for you.

Under Virus & threat protection updates, it tells us the last time that the system was scanned using definitions. If we click Protection updates, we can see even more information, such as the version, when it was created, and when it was last updated. If we want to manually force an update, we can click Check for updates.

Windows Security works reasonably well. However, some folks still prefer to disable it and install a third-party anti-malware package. If you choose this route, remember that before you install the package on your system, you need to make sure that Windows Security is turned off by going to Virus & threat protection and turning Real-time protection off, as we did earlier in this demo.

This is important because if you have two anti-malware packages running on your system at the same time, they're likely to conflict. Each will probably think that the other one is a virus.

There are some good free anti-malware packages, but keep in mind that you're likely to get better service from a paid package than a free one. But at the end of the day, the important thing is that you protect your computer from malware in some way.

That's it for this demonstration on malware. We talked about implementing anti-malware software by looking at the Windows Security app, which comes with Windows by default. Then we took a closer look at the app's features in Virus & threat protection. We also talked briefly about third-party anti-malware packages.

2.3.5 Use Windows Security (Demo Video)

Transcript:

In this demonstration, we're going to practice working with Windows Defender Firewall, which is a host-based firewall, so it's implemented as software and designed to protect an individual system. It's good to know that previously, Windows Defender Firewall was referred to as just Windows Firewall. So if you're on an older operating system, it'll go by that name, but they work basically the same. Like any firewall, it's job is to prevent somebody out on the internet or on the network from initiating an unwanted connection with your system. It just shuts any threats down before they can even get in.

Okay, we can manage these settings by searching for Control Panel, selecting System and Security, and then selecting Windows Defender Firewall. You'll notice that the firewall state is currently off. This isn't good. We want to turn the firewall back on, so let's go over here and click on Turn Windows Defender Firewall on or off.
You'll see that there are two different network profiles where the firewall is applied—our private and public network settings. We can have the private settings be a little more lax because we're assuming that the company already has a firewall in place that's blocking a lot of connections. We mostly just want to protect this individual host, which is why we'd customize the public settings more granularly. This is a bigger issue because public networks—like those at restaurants, hotels, or airports—are like the wild, wild west of information technology. You have no idea who else is on there or what their intentions are.
For both of the profiles, you can see that firewall protection is currently turned off. Again, that's not a good thing. Let's change that by selecting On for both. These default settings here work fairly well for a private network, and we'll be notified if Windows Defender Firewall blocks an app that's trying to communicate through the network. Then we can just make a list of apps with permission to pass through if we need. That's appropriate to do because there are obviously certain applications we do want to be able to receive data from. However, this might not be the case with a public network. If I'm on a public network, I most likely want to turn this option on and block all incoming connections, including those on the list of allowed apps. There's probably not anyone out there on a public network that should be initiating a connection with my computer, even with an allowed app. We'll go ahead and leave this option on for public network profiles. Let's click OK, and now the Windows Defender Firewall state is set to On for incoming connections.
Let's go deeper into how we make our list of allowed apps. There may be times when you install an app, and it needs to communicate with other hosts on the network. Like you saw, we just blocked everything by default. To change that, we come over here to Allow an app or feature through Windows Defender Firewall and select that option.
Here you can see a list of applications and features that the Windows system is aware of at this point in time and whether or not they're allowed through the firewall. For example, I'll scroll down to Remote Assistance. Remote Assistance traffic is currently allowed through the host firewall for both private and public profiles. I've enabled Remote Desktop specifically because I do a lot of remoting into my machines for testing purposes. It's usually not too difficult to find an application that you want to allow to pass through. Sometimes, though, you can't find the app you want in the list because Windows hasn't recognized it yet.
If that's the case, you can come down here and click Allow another app. Now you need to locate the app yourself. I have an app here in my Downloads folder called VNC Viewer, which allows me to connect to desktops remotely not only on Windows, but also on Linux and UNIX systems that aren't designed for use with Remote Desktop. I'll go ahead and select my VNC Viewer app and click Add. It automatically selected Public, and I can manually choose Private as well. That's it! I just click OK to finalize everything. Now that we've configured the firewall settings we want, we're ready to go.
That's all for now. In this demo, we talked about how to manage Windows Defender Firewall. First, we went over how to turn the firewall on and off, and we talked about increasing the firewall's security level on different network profiles. Then we ended this lesson by going over how to add exceptions so that specific applications can pass through.

2.3.6 Configure Microsoft Defender (Simulation)

Scenario

You recognize that the threat of malware is increasing. As such, you would like to use Windows Virus & Threat Protection to protect your computer from malware.

In this lab, your task is to:

- Enable and configure Windows Virus & Threat Protection as follows:
  - Add a file exclusion for **D:\Graphics\cat.jpg** .
  - Add a process exclusion for **welcome.scr** .
  - Locate the current threat definition version number.
    - Answer Question 1.
  - Check for updates.
    - Answer Question 2.
  - Perform a quick scan.

Explanation

Complete this lab as follows:

1. Access the *Virus & threat protection* options.
   a. Right-click **Start** , and then select **Settings** .
   b. Select **Update & Security** .
   c. From the left pane, select **Windows Security** .
   d. From the right, select **Virus & threat protection** .
2. Add a file exclusion for D:\Graphics\cat.jpg.
   a. Under *Virus & threat protection settings* , select **Manage settings** .
   b. Scroll down to Exclusions and then select **Add or remove exclusions** .
   c. Select **Add an exclusion** , and then select **File** .
   d. From the left pane, browse to and select **Data (D:)** > **Graphics** .
   e. From the right pane, select **cat.jpg** , and then select **Open** .
3. Add a process exclusion for welcome.scr.
   a. From the Exclusions dialog, select **Add an exclusion** , and then select **Process** .
   b. In the *Enter process name* field, type **welcome.scr** and select **Add** .
4. Check for protection updates.
   a. From the top left of Windows Security, select the **back arrow** twice to return to the *Virus & threat protection* page.
   b. Scroll down to *Virus & threat protection updates* and then select **Check for updates** to access the Protection updates page.
   c. From the top right, select **Answer Questions** .
   d. Answer Question 1.
   e. Select **Check for updates** .
   f. Answer Question 2.
5. Perform a quick virus scan.
   a. From the top left of the Windows Security dialog, select the **back arrow** to return to the *Virus & threat protection* page.
   b. Select **Quick scan** .
   c. Wait for the scan to complete.
6. From the Lab Questions dialog , select **Score Lab** .

2.3.7 Analyze Indicators of Malware-Based Attacks

2.3.8 Practice Questions (Section Quiz)

q_mal_bloatware_secp8

Which type of malware is software installed alongside a package selected by the user or bundled with a new computer system?

Answers:

- Logic bomb
- Trojan horse
- Spyware
- ***Bloatware**

Explanation:

Bloatware (or PUP) is software installed alongside a package selected by the user or perhaps bundled with a new computer system. Unlike a Trojan, the presence of a PUP is not automatically regarded as malicious. It may have been installed without active consent or with consent from a purposefully confusing license agreement.

A logic bomb is malware that lies dormant until triggered.

A Trojan horse is a malicious program that is disguised as legitimate software.

Spyware monitors the actions performed on a machine and then sends the information back to its originating source.

q_mal_crypto-ransomware_secp8

What is the primary function of crypto-ransomware?

Answers:

- To steal sensitive information from the infected system.
- ***To encrypt files on the infected system and demand a ransom for the decryption key.**
- To create a backdoor for remote access to the infected system.
- To spread spam emails from the infected system.

Explanation:

Crypto-ransomware encrypts files on the infected system and then demands a ransom, typically in a form of cryptocurrency like Bitcoin, in exchange for the decryption key.

Crypto-ransomware does not primarily aim to steal sensitive information. It focuses on encrypting files and demanding a ransom. However, some advanced forms of ransomware may also steal data.

While some forms of malware are designed to create a backdoor for remote access, this is not the primary function of crypto-ransomware. Its main goal is to encrypt files and demand a ransom.

Spreading spam emails is a common function of some types of malware, but it is not the primary function of crypto-ransomware.

q_mal_fileless_secp8

Which virus operates only in memory and usually exploits a trusted application like PowerShell to circumvent traditional endpoint security solutions?

Answers:

- Remote Access Trojan (RAT)
- ***Fileless malware**
- Ransomware
- Worm

Explanation:

Fileless malware operates only in memory to avoid detection by traditional endpoint security solutions that are focused on matching signatures to files that have been written to the hard drive.

A worm is a self-replicating program.

Ransomware denies access to a computer system until the user pays a ransom.

A Remote Access Trojan (RAT) is a malware program that includes a backdoor that allows administrative control over the target computer.

q_mal_logic_bomb_secp8

What differentiates a logic bomb from other types of malware?

Answers:

- Logic bombs are always visible to the user.
- ***Logic bombs can only be triggered by a specific event or condition.**
- Logic bombs are always associated with ransomware.
- Logic bombs can only infect networked systems.

Explanation:

Logic bombs are unique in that they are programmed to execute (or "explode") when a specific condition or event occurs, such as a certain date and time, a specific user logging in, or a particular application being launched.

Logic bombs, like many other types of malware, often operate in the background without the user's knowledge until they are triggered.

While it's possible for a logic bomb to be part of a ransomware attack, they are not inherently associated with ransomware. Logic bombs can be used in various types of malicious software.

Logic bombs can infect any system, not just networked ones. They can be placed in any piece of software and triggered by a wide range of events or conditions.

q_mal_logic_secp8

Which of the following describes a logic bomb?

Answers:

- ***A program that performs a malicious activity at a specific time or after a triggering event.**

- A type of malicious code similar to a virus whose primary purpose is to duplicate itself and spread while not necessarily intentionally damaging or destroying resources.
- A program that appears to be a legitimate application, utility, game, or screensaver that performs malicious activities surreptitiously.
- A program that has no useful purpose but attempts to spread itself to other systems and often damages resources on the systems where it is found.

Explanation:

A logic bomb is a program that performs a malicious activity at a specific time or after a triggering event. Logic bombs can be planted by a virus, a Trojan horse, or an intruder. Logic bombs may perform their malicious activity at a specific time and date or when a specific event occurs on the system, such as logging in, accessing an online bank account, or encrypting a file.

A type of malicious code similar to a virus whose primary purpose is to duplicate itself and spread, while not necessarily intentionally damaging or destroying resources, is a worm.

A program that appears to be a legitimate application, utility, game, or screensaver that performs malicious activities surreptitiously is a Trojan horse.

A program that has no useful purpose but attempts to spread itself to other systems and often damages resources on the systems where it is found is a virus.

q_mal_ransomwae_secp8

Which of the following is a type of malware that prevents the system from being used until the victim pays the attacker money?

Answers:

- Remote Access Trojan (RAT)
- Denial-of-service attack (DoS attack)
- ***Ransomware**
- Fileless virus

Explanation:

A type of malware used to prevent the system from being used until a ransom is paid by the victim is known as ransomware.

While it does perform a denial-of-service, a DoS attack does not necessarily demand payment.

A Remote Access Trojan (RAT) is a malware program that includes a backdoor that allows administrative control over the target computer.

A fileless virus uses legitimate programs to infect a computer.

q_mal_rat_secp8

Which kind of malware provides an attacker with administrative control over a target computer through a backdoor?

Answers:

- Potentially unwanted program (PUP)

- Crypto-malware
- Trojan horse
- ***Remote Access Trojan (RAT)**

Explanation:

A Remote Access Trojan (RAT) provides a backdoor for an attacker to remotely control a computer with administrative control. The other types of malware could be used in conjunction with a RAT, but they do not provide remote control access.

PUP is software that contains adware, installs toolbars, or has other unclear objectives.

Crypto-malware is ransomware that encrypts files until a ransom is paid.

A Trojan horse is a malicious program that is disguised as legitimate or desirable software.

q_mal_rootkit_secp8

Which of the following are characteristics of a rootkit? (Select two.)

Answers:

- ***Requires administrator-level privileges for installation.**
- ***Resides below regular antivirus software detection.**
- Monitors user actions and opens pop-ups based on user preferences.
- Uses cookies saved on the hard drive to track user preferences.
- Collects various types of personal information.

Explanation:

A rootkit is a set of programs that allow attackers to maintain hidden, permanent, administrator-level access to a computer. A rootkit:

- Is almost invisible software.
- Resides below regular antivirus software detection.
- Requires administrator privileges for installation and then maintains those privileges to allow subsequent access.
- Might not be malicious.
- Often replaces operating system files with alternate versions that allow hidden access.

Spyware collects various types of personal information, such as internet surfing habits and passwords, and sends the information back to its originating source.

Adware monitors actions that denote personal preferences and then sends pop-ups and ads that match those preferences.

Both spyware and adware can use cookies to collect and report a user's activities.

q_mal_spyware_secp8

Which of the following BEST describes spyware?

Answers:

- ***It monitors the actions you take on your machine and sends the information back to its originating source.**
- It monitors user actions that denote personal preferences and then sends pop-ups and ads to the user that match their tastes.
- It is a program that attempts to damage a computer system and replicate itself to other computer systems.
- It is a malicious program disguised as legitimate software.

Explanation:

Spyware monitors the actions you take on your machine and sends the information back to its originating source.

Adware monitors the actions of the user that denote their personal preferences and then sends pop-ups and ads to the user that match their tastes.

A virus is a program that attempts to damage a computer system and replicate itself in other computer systems.

A Trojan horse is a malicious program disguised as legitimate software.

q_mal_worms_secp8

In 2001, a worm exploited vulnerabilities in Microsoft Internet Information Services (IIS) to infect over 250,000 systems in under nine hours.

What was this worm called?

Answers:

- Melissa
- ***Code Red**
- Nimda
- Michelangelo

Explanation:

The worm known as Code Red replicated across the internet with incredible speed using a vulnerability in Microsoft IIS.

In 1991, the Michelangelo virus was designed to infect MS-DOS systems and remain dormant until March 6, the birthday of Renaissance artist Michelangelo.

In 1999, the Melissa worm was the first widely distributed macro virus that was propagated in the form of an email message containing an infected Word document as an attachment.

In 2001, the Nimda worm took advantage of weaknesses found in the Windows platform and propagated itself in several ways, including email, infected websites, and network shares.

q_mal_prot_Anti-virus_secp8

You have installed antivirus software on the computers on your network. You update the definition and engine files and configure the software to update those files every day.

What else should you do to protect your systems from malware? (Select two.)

Answers:

- ***Educate users about malware.**
- ***Schedule regular full-system scans.**
- Enable account lockout.
- Disable UAC.
- Enable chassis intrusion detection.

Explanation:

You should schedule regular full-system scans to look for any malware. In addition, educate users about the dangers of downloading software and the importance of anti-malware protections.

You should enable User Account Control (UAC) to prevent unauthorized administrative changes to your system.

Use account lockout to help protect your system from hackers trying to guess passwords.

Use chassis intrusion detection to identify when the system case has been opened.

q_mal_prot_reimage_secp8

Which of the following malware recovery techniques is often faster and more effective than malware removal and cleanup of an infected computer?

Answers:

- ***Re-imaging the computer**
- Enabling privacy controls
- Remove removable drives
- Block specific executable files

Explanation:

Re-image a machine if your organization uses imaging solutions. Re-imaging or installing from scratch is often faster and more effective than malware removal and cleanup.

The following are preventative measures, not recovery techniques:

- Enabling privacy controls in Windows Internet Explorer such as deleting browser history.
- Removing removable drives to prevent unauthorized software from being installed on a system.
- Block executable files that have been copied from another computer.

q_mal_prot_web_filters_secp8

To prevent malware infection in your network system, you decide that it's critical to prevent malware attacks, such as ransomware and phishing, by restricting access to sites that might be malicious.

Which of the following BEST represents this type of prevention technique?

Answers:

- ***Web filters**

- Pop-up blocker
- Patching the operating system
- Updating your web browser

Explanation:

By installing web filters, you can prevent malware attacks, such as ransomware and phishing attacks, which often originate from malicious websites. By restricting access to these sites, web filters significantly reduce the risk of malware infections.

The following are also malware prevention techniques, but do not meet your prevention requirements:

- Using a pop-up blocker prevents adware.
- Installing the latest patches for the operating system.
- Updating your web browser

q_windefender_01

What is the current security intelligence version?

Answers:

- 1.229.426.0
- 1.125.333.1
- 1.229.426.0
- 1.300.000.1

q_windefender_02

After the update, what is the current security intelligence version?

Answers:

- 1.229.508.0
- 1.125.333.1
- 1.229.426.0
- 1.229.508.0
- 1.300.000.1

3.0 Cryptographic Solutions

3.1 Cryptography

As you study this section, answer the following questions:

- What is the difference between symmetric and asymmetric encryption?
- Which part of a simple cryptographic system must be kept secret—the cipher, the ciphertext, or the key?
- Which algorithms can be used to generate a hash?
- What is the process of digitally signing a message?
- What is a legitimate use for steganography?
- What are uses of blockchain in addition to cryptocurrency?
- What are the properties of a public/private key pair?

In this section, you will learn to:

- Use steganography to hide a file.
- Hide files with OpenStego.

Key terms for this section include the following:

Term	Definition
Cryptography	The science and practice of altering data to make it unintelligible to unauthorized parties.
Plaintext	Unencrypted data that is meant to be encrypted before it is transmitted, or the result of the decryption of encrypted data.
Ciphertext	Data that has been enciphered and cannot be read without the cipher key.
Algorithm	Operations that transform a plaintext into a ciphertext with cryptographic properties; also called a cipher.
Cryptanalysis	The science, art, and practice of breaking codes and ciphers.
Encryption	Scrambling the characters used in a message so that the message can be seen but not understood or modified unless it can be deciphered. Encryption provides for a secure means of transmitting data and authenticating users. It is also used to store data securely. Encryption uses different types of cipher and one or more keys. The size of the key is one factor in determining the strength of the encryption product.
Key	In cryptography, a specific piece of information that is used in conjunction with an algorithm to perform encryption and decryption.

Symmetric encryption	Two-way encryption scheme in which encryption and decryption are both performed by the same key. Also known as shared-key encryption.
Key length	Size of a cryptographic key in bits. Longer keys generally offer better security, but key lengths for different ciphers are not directly comparable.
Asymmetric algorithm	Cipher that uses public and private keys. The keys are mathematically linked, using either Rivel, Shamir, Adleman (RSA) or elliptic curve cryptography (ECC) alogrithms, but the private key is not derivable from the public one. An asymmetric key cannot reverse the operation it performs, so the public key cannot decrypt what it has encrypted, for example.
Public key	During asymmetric encryption, this key is freely distributed and can be used to perform the reverse encryption or decryption operation of the linked private key in the pair.
Private key	In asymmetric encryption, the private key is known only to the holder and is linked to, but not derivable from, a public key distributed to those with whom the holder wants to communicate securely. A private key can be used to encrypt data that can be decrypted by the linked public key or vice versa.
Blockchain	A concept in which an expanding list of transactional records listed in a public ledger is secured using cryptography.
Open public ledger	Distributed public record of transactions that underpins the integrity of blockchains.
Steganography	The practice of concealing a file, message, image, or video within another file, message, image, or video.

This section helps you prepare for the following certification exam objectives:

Exam	Objective
CompTIA Security+ SY0-701	4.2 Implement Encryption Technologies 4.2.1 Encrypt data communications

TestOut Security Pro	1.4 Explain the importance of using appropriate cryptographic solutions
	• Public key infrastructure (PKI)
	  ○ Public key
	  ○ Private key
	  ○ Key escrow
	• Encryption
	  ○ Asymmetric

	• Symmetric • Algorithms • Key length • Obfuscation • Steganography • Hashing • Salting • Digital signatures • Blockchain 2.4 Given a scenario, analyze indicators of malicious activity • Cryptographic attacks • Downgrade • Collision • Birthday

3.1.1 Cryptography Concepts (Lesson Video)

Transcript:

A security specialist's main goal is to keep data safe and out of the hands of hackers and other threats. To do that, you can lock down a system using multiple methods, but there's always a chance that a hacker will still get through. You can use cryptography to add an additional layer of protection and make it even more difficult for hackers to steal your data, even if they get inside.

In this video, we'll discuss what cryptography is, the basic concepts associated with cryptology, and some common cryptology methods.
Cryptography is defined as the process of writing or solving messages using a secret code. Cryptography isn't new. The earliest known use of cryptography was by the Egyptians in 1900 BC to deliver messages using encryption.
Encryption is the process of converting normal text into text that makes no sense at all, which is called ciphertext. A cipher is the method, or algorithm, used to encrypt the data. I know that might sound a little confusing, since these terms are often used interchangeably, so let's look at an example using a puzzle.
When you're completing a puzzle, you normally look at the completed picture on the box and then put the pieces together to match the picture. If you wanted to disguise the puzzle from prying eyes, you could use cryptography. In this case, you could encrypt the puzzle by flipping all the pieces over and scrambling them up, so no one can see the images printed on the puzzle pieces. Then, to allow you or anyone else to put the puzzle together, you'll need a method that's only given out to certain people. That's the cipher. We'll used a numbered cipher here. Using that cipher, anyone would be able to put the puzzle together.
One of the most common encryption ciphers is the Caesar cipher.
This cipher was created by Julius Caesar. When he wanted to sent a secret message, Caesar would shift each letter down the alphabet by three places. Then he could safely send the message to his commanders because anyone who intercepted the message couldn't read it anyway. Since only the commanders knew the cipher was to shift the letters up the alphabet by three, only they could read it.
Today, encryption is much more advanced than the Caesar cipher. You'll hear a lot about encryption keys, hashes, and digital signatures. To understand modern encryption, you need to understand these concepts.
Let's talk about encryption keys first. We install locks on our doors to keep our homes safe. These locks require a specific key. Encryption works using the same concept. When we want to encrypt data, we use an encryption key. Encryption keys are random strings of bits that are used to lock and unlock data. These keys are generated using ciphers, such as the Advanced Encryption Standard, or AES. They ensure each key is unique and difficult to crack.

There are two types of encryption methods, symmetric and asymmetric. Symmetric encryption uses the same key to encrypt and decrypt data. Asymmetric encryption uses one key to encrypt and then a different key to decrypt. These are referred to as public and private keys.
When you're working with these encryption methods, different techniques are used to help safeguard your data. One technique is known as hashing.
Hashing is the process of converting one value into another using a mathematical algorithm like MD5 or SHA. Hashes have several characteristics that make them very useful. For example, hashes are deterministic, meaning that the same data being hashed always results in the same hash value. Hashes can also be created very quickly and cannot be decrypted. Likewise, it's infeasible to find two messages with the same hash value. Even a small change to a message will change the hash value so extensively that the new hash value appears uncorrelated with the old hash value.
Because of these features, hashes are used in many applications.
A hash function is often used to verify passwords. Since storing or transmitting passwords in cleartext could result in a massive security breach, most systems only store the hash of the password. When a user needs to be authenticated, the password entered by the user is hashed and compared with the stored hash.
One of the problems with using hashed passwords is that several online sites have collected massive databases containing a hash for tens of million of possible passwords. Once a hash has been captured, it can be compared with the hashes found in the database, quickly resulting in the password used to create the hash. To keep this from happening, most hashes also incorporate something called a salt.
Salting the hash means adding a random number of characters to the password before the hash is created. For example, if this is the password to be hashed, a salt such as this may be added. This becomes the string to be hashed. Since the salt is randomly generated each time, even if the same password is used and can be varying lengths, it's virtually impossible to create a database containing all the possible salted passwords.
Hashes are also used to verify that a document hasn't been corrupted or tampered with by creating a hash for the document. When the same hash algorithm is calculated at the receiving end, the hashes should match. If not, then the data was either corrupted or tampered with during transmission and should not be trusted. In a similar fashion, hashes are also used to digitally verify a signature, like when you digitally sign an important document using the internet. In this case, only the signature is hashed instead of the entire document.
While there are many different cryptography methods that can be used to secure data, one of the most powerful methods used today is Elliptic Curve Cryptology, or ECC. Many websites use this method to secure connections and the data they send back and forth.
To truly understand ECC and how it works would require us to dive into some really complicated math that's beyond the scope of this lesson. For now, you just need to know that this method is the next generation of cryptology, and the algorithm used can generate smaller keys that are more secure than other cryptology methods.
The last encryption technique we'll discuss is call steganography. Steganography is the technique of hiding or concealing a file, message, image, or video within another file, message, image, or video. If you've ever used invisible ink to write a hidden message, you've used steganography.
One method of steganography is to use a special program to hide a message in another file, such as this image. When the recipient receives the image, they can use the same software to find the hidden message. If the file is intercepted by a hacker, all they'll see is the image.
That's it for this lesson. In this lesson, we discussed what cryptography is and how encryption and ciphers are used. We covered the key concepts of cryptography, including encryption keys, hashes, and digital signatures.
And then we looked at a few cryptology methods, including hashing, elliptical curve cryptology, and steganography.

3.1.2 Cryptography Facts

The goal of all IT security specialists is to keep data safe. Hackers find ways to circumvent firewalls, IPS devices, and other security protocols put in place. Cryptography is one additional layer of defense that can be used to protect data.

This lesson covers the following topics:

- Cryptography overview
- Cryptography concepts
- Cryptography methods

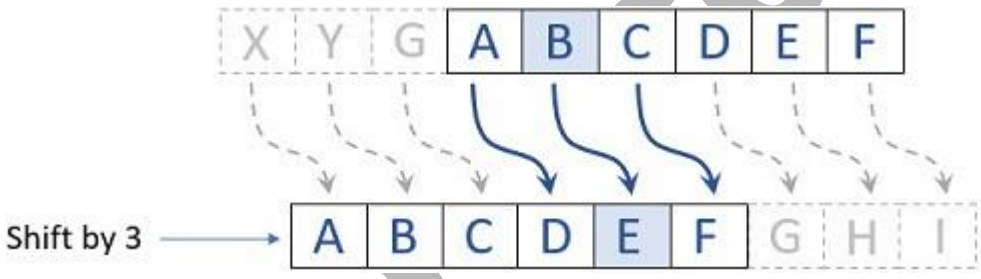
Cryptography Overview

Cryptography is the process of writing or solving messages using a secret code. This is the opposite of security through obscurity. Security through obscurity means keeping something a secret by hiding it. This is considered impossible (or at least high risk) on a computer system. With cryptography, it does not matter if third parties know of the existence and location of the secret because they can never understand what it is without the means to decode it. A form of cryptography called encryption has been used throughout the ages, mainly to keep messages out of the hands of enemies. Encryption is the process of converting normal readable text into something unintelligible called ciphertext. A cipher is the method or algorithm used to encrypt or convert the data.

The following terminology is used to discuss cryptography:

- **Plaintext (or cleartext)** - is an unencrypted message.
- **Ciphertext** - is an encrypted message.
- **Algorithm** - is the process used to encrypt and decrypt a message.
- **Cryptanalysis** - is the art of cracking cryptographic systems.

One of the more popular forms of encryption is the Caesar cipher. This encryption method works by shifting each letter in the alphabet a certain number of spaces to the right or left. In the example below, the cipher is shifting to the right by three letters. A becomes D, B becomes E, C becomes F, etc.



To decrypt the message, the reader must know how many spaces to shift the letters. For example, to encrypt the word TESTOUT using the Caesar Cipher with a shift of three to the right, TESTOUT would become WHVWRXW.

Below is the complete Caesar cipher using a shift of three letters to the right (you can see below which letters are used when they are shifted three spaces):

This is a very simple example of cryptography and is easily decrypted. With today's computing power, encryption methods used are much more complicated and powerful.

Cryptography Concepts

There are three main concepts to understand when dealing with today's encryption methods: encryption keys, hashing, and digital signatures.

Cryptography Concept	Description
Encryption keys	Encryption keys are used to encrypt and decrypt data. The key is a string of bits randomly generated using a specific cipher, such as Advanced Encryption Standard (AES). There are two types of encryption methods used with keys: symmetric and asymmetric. • Symmetric encryption uses the same key to encrypt and decrypt data. • Asymmetric encryption uses one key to encrypt the data and a different key to decrypt the data. These keys are known as a public key and private key.
Hashing	Hashing is the process of converting one value into another using a mathematical algorithm like MD5 or SHA. This fixed length of data is called the hash. • Hashing is used on data that does not need to be decrypted, such as passwords. • When a piece of data is run through a hashing algorithm, it always generates the same hash. If even one letter in a file has been altered, the resulting hash would be different. Because of this, hashing can be used to verify that data has not been altered during transmission. • A hash cannot be decrypted. However, when using hashing for passwords, many online sites have collected massive databases containing a hash for tens of millions (or more) of possible passwords. Once a hash has been captured, it can be compared with the hashes found in the database, quickly resulting in the password used to create the hash.
Salt	Salt, or salting the hash, means that a random number of characters are added to the password before the hash is created. For example, if the password to be hashed was p@ssw0rd, a salt, such as E1343135E119C253, may be added. Therefore, the string to be hashed would be p@ssw0rdE1343135E119C253. Since the salt is randomly generated each time, even if the same password is used and is of varying lengths, it's virtually impossible to create a database containing all the possible salted passwords.
Digital signatures	By combining a user's private encryption key and a hash of the data, a user can create a digital signature. A digital signature verifies that the data is legitimate and provides non-repudiation. This means that the sender cannot deny having sent the file.

Cryptography Methods

There are many different cryptography methods used today. One important thing to keep in mind is that all cryptography uses advanced math concepts to generate encryption keys and hashes.

Cryptography Method	Description
Elliptic Curve Cryptography (ECC)	Elliptic Curve Cryptography is one of the newer methods being implemented. ECC can generate smaller keys that are more secure than most other methods. Many websites today use ECC to secure connections and data transmissions.

Cryptography Method	Description
Perfect Forward Secrecy	This cryptography method is used quite often in messaging apps. Instead of the same key being used for an entire conversation or session on a website, each transmission is encrypted with a different unique key.
Steganography	Steganography is the technique of hiding or concealing a file, message, image, or video within another file, message, image, or video. Special programs are often used to hide messages in media files. If a hacker intercepts the message, all they see is the media. They don't know that there is a hidden message.

3.1.3 Symmetric vs Asymmetric Encryption (Lesson Video)

Transcript:

Keeping data and messages safe from prying eyes is the goal of cybersecurity. We can hide data from hackers by encrypting it. Encryption is the process of encoding data into a format that's unreadable. All encryption relies on a unique key to encrypt and decrypt the data. This key is basically a password that's combined with the cipher to encrypt the data. In this lesson, we're going to look at some encryption methods including symmetric encryption, asymmetric encryption, hybrid cryptosystems, and ephemeral keys.

Symmetric encryption uses the same key to encrypt and decrypt data. This is the simplest and oldest form of encryption. Let's look at how this works.
Travis has a confidential file that he needs to send to Craig. To ensure that the file is sent safely, Travis encrypts the file using his secret symmetric encryption key and sends it to Craig. To open the file, Craig must use the same encryption key to decrypt the file.
One of the biggest problems with symmetric encryption is that both parties must use the same key. If Travis and Craig send encrypted data often, they've probably set up this secret key in advance. But if not, Travis needs to let Craig know what the secret key is. Sending the key with the data defeats the purpose because if a hacker intercepts the message, they can decrypt the file.
Imagine what a pain it would be to distribute the secret key if multiple people were to need access to it. Not only is this difficult to do, but the more people that have the key, the more likely it is for the key to be compromised.
Symmetric encryption is very secure and works extremely well when you need to encrypt a large amount of data because it requires less CPU power than asymmetric encryption.
There are many symmetric-key algorithms used, but some of the more common ones are Data Encryption Standard, Rivest Cipher, and Advanced Encryption Standard.
The Advanced Encryption Standard, or AES, has for the most part replaced all other types of symmetric encryption. AES is a subset of the Rijndael block cipher, It was developed in 2001 during a competition run by the US National Institute of Standards and Technology, or NIST. AES offers three key lengths of 128, 192, or 256 bits. AES is used in all sorts of ways including 802.11 communication, BitLocker, and even some games engines.
Some other symmetric algorithms you may come across are Blowfish, IDEA, CAST, and Twofish. While these algorithms aren't used much anymore, you should at least know they exist.
Asymmetric encryption makes use of two different keys, a public key and a private key. The public key is used to encrypt the data and the private key is used to decrypt it. Since these keys mirror each other, the private key only decrypts data that was encrypted with the matching public key. Let's see this in action.
Travis is sending his confidential file to Craig. To do that, Travis must first get Craig's public key. Travis then uses Craig's public key to encrypt the data, and the file is sent to Craig. When Craig gets the file, he uses his private key to decrypt it.
As another example, asymmetric encryption is used in most communication over the internet.
For example, when you log on to a website, your browser sends a request for the public key which is then sent by the web server. Your login information is entered and encrypted using that public key, which is then sent to the server. The server in turn decrypts the login information using its private key. You're now logged into the web server. As you can see

from these examples, users don't ever reveal their private keys in this exchange. Data security is increased with asymmetric encryption, which is the primary reason for using it.
Another reason for using asymmetric encryption is to create digital signatures.
A digital signature is a method used to ensure that a received message or document hasn't been modified from the time it was signed.
This is done by generating a unique hash of the message or document and encrypting it with the sender's private key. When the recipient receives the message, they can verify the digital signature to ensure that the data or message is legitimate. Since anyone can decrypt these messages or documents with the public key, digital certificates don't secure data. They simply verify that the data is legitimate and came from the proper source. Guaranteeing the data source in this way provides non-repudiation, or the ability to ensure that the document's sender cannot deny sending the document.
There are four main asymmetric encryption algorithms you need to be aware of. These are Diffie-Hellman, RSA, DSA, and ECC.
Diffie-Hellman was the first widely used asymmetric algorithm. It was released in 1976 by Whitfield Diffie and Martin Hellman. This algorithm allows two parties who've never met to safely create a shared key over a public channel, such as the internet. We can see how this key is created using a choice of colors.
For example, our two users each agree on a paint color such as yellow. Each user then decides on a secret color to mix with their common color, creating a color they can share publicly. They send each other their results and then mix in their secret color. Each user ends up with the same new secret color. This new secret color, or key, is then used to encrypt and decrypt their messages. If a hacker were to intercept any of these messages without knowing each user's secret color, they wouldn't be able to reverse the process and figure out the final secret color. Diffie-Hellman is frequently implemented in security protocols such as TLS, IPSec, SSH, and more.
In 1977, Ron Rivest, Adi Shamir, and Leonard Adleman released one of the first public-key cryptosystems, which is known by the initial letters of the developer's surnames RSA. RSA defined the process of using a public key to encrypt data and a secret key to decrypt it. RSA is still one of the most widely used algorithms for securing data transmissions and creating digital signatures.
The Digital Signature Algorithm, or DSA, is a Federal Information Processing Standard for digital signatures. It was proposed in 1991 by NIST and became the government standard in 1993. It uses a different algorithm than RSA but provides the same level of security.
Elliptic Curve Cryptography, or ECC, is the latest encryption method. The algorithms used with this method can generate smaller keys that are just as secure as other methods. Many websites have adopted ECC to secure data being sent back and forth.
Asymmetric encryption methods aren't very efficient because they rely on some complicated mathematical computations. But they do make it easier to exchange keys. In contrast, Symmetric methods are efficient, but they become inconvenient when the time comes to get the keys out. A hybrid cryptosystem combines the efficiency of symmetric methods and the convenience of asymmetric methods.
Let's see how it works.
Travis needs to send a confidential file to Craig. Before doing so, Travis uses his symmetric private key to encrypt the data. Next, Travis encrypts the secret key using Craig's public key. The file is then sent to Craig. When Craig gets the message, he first uses his private key to decrypt the symmetric secret key and then uses the symmetric key to decrypt the message.
As long as Craig's private key is kept secret, the data is secure. Most secure communication methods such as TLS utilize a hybrid cryptosystem nowadays.
Generally, when we establish a session and exchange keys, all communication during that session uses the same encryption keys. These are known as static keys. The problem is that the longer a key is used, the more susceptible it is to attack. To combat this, we use ephemeral keys.
These are keys that are generated for each new session or transaction. Perfect forward secrecy makes use of ephemeral keys. Perfect forward secrecy and ephemeral keys are used quite often in instant messaging apps.
Every message that's sent generates its own encryption key. It doesn't matter if a hacker intercepts any of the keys because the next message has a completely different one. The hacker is unable to eavesdrop on the entire conversation or session.
That's it for this lesson. In this lesson, we first looked at symmetric encryption which uses the same key to encrypt and decrypt data. We then looked at asymmetric encryption which uses a public key and a private key to encrypt and decrypt data. We also covered hybrid cryptosystems that combine the efficiency of symmetric methods and the convenience of asymmetric methods. Finally, we covered ephemeral keys. These are keys that are generated for each new session or transaction.

3.1.4 Symmetric and Asymmetric Encryption Facts

There are three main types of cryptographic algorithms with different roles to play in the assurance of the security properties: confidentiality, integrity, availability, and non-repudiation. These types are hashing algorithms and two types of encryption ciphers: symmetric and asymmetric.

This lesson covers the following topics:

- Symmetric encryption
- Key length
- Asymmetric encryption
- Hybrid cryptosystems
- Ephemeral keys

Symmetric Encryption

An encryption algorithm or cipher is a type of cryptographic process that encodes data so that it can be stored or transmitted securely and then decrypted only by its owner or its intended recipient. Using a key with the encryption cipher ensures that decryption can only be performed by an authorized person.

Substitution and Transposition Algorithms

It is helpful to consider simple substitution and transposition algorithms to understand how an algorithm works. A substitution cipher involves replacing characters or blocks in the plaintext with different ciphertexts. Simple substitution ciphers rotate or scramble letters of the alphabet. For example, ROT13 rotates each letter 13 places, so A becomes N, for instance. The ciphertext "Uryyb Jbeyq" can be decrypted as the plaintext "Hello World."

In contrast to substitution ciphers, the units in a transposition cipher stay the same in plaintext and ciphertext, but their order is changed according to some mechanism. Consider how the ciphertext "HLOOLELWRD" has been produced:

H L O O L

E L W R D

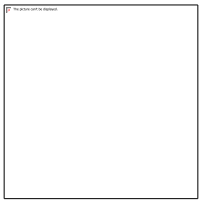
The letters are written as columns, and then the rows are concatenated to make the ciphertext.

Modern encryption algorithms use these basic techniques of substitution and transposition in complex ways that can defeat attempts at cryptanalysis.

Symmetric Algorithms

A symmetric algorithm is one in which encryption and decryption are both performed by the same secret key. The secret key must be kept known to authorized persons only. If the key is lost or stolen, the security is breached. Symmetric encryption is used for confidentiality. For example, Alice and Bob can share a confidential file in the following way:

- Alice and Bob meet to agree which cipher to use and a secret key value. They both record the value of the secret key, making sure that no one else can discover it.
- Alice encrypts a file using the cipher and key.
- Alice sends only the ciphertext to Bob over the network.
- Bob receives the ciphertext and is able to decrypt it by applying the same cipher with his copy of the secret key.



Symmetric encryption operation and weaknesses (Images © 123RF.com).

Symmetric encryption is very fast. It is used for bulk encryption of large amounts of data. The main problem is how Alice and Bob "meet" to agree upon or exchange the key. If Mallory intercepts the key and obtains the ciphertext, the security is broken.

Note that symmetric encryption cannot be used for authentication or integrity. Alice and Bob are able to create exactly the same secrets because they both know the same key.

The most common symmetric algorithm is the Advanced Encryption Standard (AES), also known as the Rijndael cipher. It was developed by Jaon Daemen and Vincent Rijmen in 2001 as part of a NIST competition held to find a replacement for DES. AES offers three different key lengths of 128, 192, and 256 bits. AES is used in many applications, including 802.11 communications, Bitlocker, and game engines.

Other common symmetric algorithms include Data Encryption Standard (DES), Rivest's Cipher (RC), International Data Encryption Algorithm (IDEA), Blowfish, Twofish, and CAST.

Key length

Encryption algorithms use a key to increase the security of the process. For example, if you consider the substitution cipher ROT13, you should realize that the key is 13. You could use 17 to achieve a different ciphertext from the same method. The key is important because it means that even if the cipher method is known, a message still cannot be decrypted without knowledge of the specific key.

A keyspace is the range of values that the key could be. In the ROT13 example, the keyspace is 25 (ROT1. . . ROT25). Using ROT0 or ROT26 would result in ciphertext identical to the plaintext. Using a value greater than 26 to shift through the alphabet multiple times is equivalent to a key from the 1-25 range. ROT0 and ROT26+ are weak keys and should not be used.

Modern ciphers use large keyspaces where there are trillions of possible key values. This makes the key difficult to discover via brute force cryptanalysis. *Brute force cryptanalysis* means attempting decryption of the ciphertext with every possible key value and reading the result to determine if it is still gibberish or plaintext.

Keys for modern symmetric ciphers use a pseudorandomly generated number of bits. The number of bits is the key length . For example, the most commonly used symmetric cipher is the Advanced Encryption Standard (AES). This can be used with two key lengths. AES-128 uses a 128-bit key length. A bit can have one of two values (0 or 1), so the number of possible key values is two multiplied by itself a number of times equivalent to the key length. This is written as 2^{128}, where 2 is the base, and ^{128} is the exponent. AES-256 has a keyspace of 2^{256}. This keyspace is not twice as large as AES-128; it is many trillions of times bigger and consequently significantly more resistant to brute force attacks.

The drawback of using larger keys is that the computer must use more memory and processor cycles to perform encryption and decryption.

Asymmetric Encryption

In a symmetric encryption cipher, the same secret key is used to perform both encryption and decryption operations. With an asymmetric algorithm , encryption and decryption are performed by two different but related public and private keys in a key pair.

When a public key is used to encrypt a message, only the paired private key can decrypt the ciphertext. The public key cannot be used to decrypt the ciphertext. The keys are generated in a way that makes it impossible to derive the private key from the public key. This means that the key pair owner can distribute the public key to anyone they want to receive secure messages from:

- Bob generates a key pair and keeps the private key secret.
- Bob publishes the public key. Alice wants to send Bob a confidential message, so they take a copy of Bob's public key.
- Alice uses Bob's public key to encrypt the message.
- Alice sends the ciphertext to Bob.
- Bob receives the message and is able to decrypt it using their private key.
- If Mallory has been snooping, they can intercept both the message and the public key.
- However, Mallory cannot use the public key to decrypt the message, so the system remains secure.

Asymmetric encryption (Images © 123RF.com)

The drawback of asymmetric encryption is that it involves substantial computing overhead compared to symmetric encryption. Where a large amount of data is being encrypted on disk or transported over a network, asymmetric encryption is inefficient. Rather than being used to encrypt the bulk data directly, the public key cipher can be used to encrypt a symmetric secret key. This allows Alice and Bob to exchange a bulk encryption session key without Mallory being able to learn it.

Asymmetric encryption can be implemented using a number of algorithms. Each algorithm has a different recommended key length. The Rivest, Shamir, Adelman (RSA) asymmetric cipher requires a 2,048-bit private key to achieve an acceptable level of security. The Elliptic Curve Cryptography (ECC) asymmetric cipher can use 256-bit private keys to achieve a level of security equivalent to a 3,072-bit RSA key.

The following table shows common asymmetric encryption algorithms:

Asymmetric Algorithm	Description
Rivest-Shamir-Adleman (RSA)	RSA was developed by Ron Rivest, Adi Shamir, and Leonard Adleman. RSA was released shortly after Diffie-Hellman in 1977. • RSA is still one of the most commonly used algorithms and helped define the process of using a public key to encrypt data and a private key to decrypt the data. • RSA is used extensively for creating digital signatures.
Elliptic Curve Cryptography (ECC)	Elliptic Curve Cryptology is one of the newer methods being implemented. It was originally introduced in 1985. It did not enter wide usage until 2004. • ECC is able to generate smaller keys that are more secure than most other methods. • Many websites today use ECC to secure connections and data transmissions.

Asymmetric Algorithm	Description
Diffie-Hellman	Released in 1976 by Whitfield Diffie and Martin Hellman. Its purpose was to allow two users who have never met to safely create a shared key over a public channel such as the internet. • Diffie-Hellman is used as follows: 1. The two users agree on two numbers: a prime number (P) and a generator (g). These numbers can be shared publicly. 2. Each user then randomly generates a private number, or key, unique to themselves. 3. Using the prime number, generator, and private key, each user generates a public key using the following formula: ▪ (G^ private number) MOD P 4. The users exchange their public keys, which are then used to create a shared secret key using the following formula: ▪ (Shared Public Key^ private number) MOD P 5. Because each public key was generated using the same prime number and generator, each user will come up with the same number for the shared secret key. 6. If a hacker intercepted any of the exchanges, they could not reverse the process without knowing each user's secret number. • Diffie-Hellman is frequently implemented in security protocols such as TLS, IPSec, SSH, and others.
Digital Signature Algorithm (DSA)	DSA was proposed in 1991 by NIST and became the government standard in 1993 • DSA is only used for creating digital signatures. • It uses a different algorithm than RSA but provides the same level of security.

Hybrid Cryptosystems

Hybrid cryptosystems combine the efficiency of symmetric encryption with the convenience of asymmetric encryption. A hybrid cryptosystem is used as follows:

1. User1 uses their symmetric private key to encrypt some data.
2. User1 then encrypts that symmetric private key using the recipient's public key and sends both to the recipient.
3. User2, the recipient, uses their private key to decrypt User 1's private key, which is then used to decrypt the message.
4. As long as User2's private key is kept secret, the data remains secure.

Hybrid cryptosystems are used with many secure communication methods today, such as TLS.

Ephemeral Keys

In traditional encrypted communications, static keys are used. This means that the same key is used throughout an entire session. The problem with this is that the longer the keys are used, the more susceptible they become to an attack. Ephemeral keys can be used to resolve this issue.

Ephemeral keys are generated for each new session or message sent. For example, perfect forward secrecy (PFC) uses ephemeral keys.

Some popular instant messaging apps make use of ephemeral keys to encrypt messages. Each message sent uses a unique key to encrypt it. If a hacker intercepts one key, the rest of the messages are still safe.

3.1.5 Cryptography Algorithm (Lesson Video)

Transcript:

In this lesson, we're going to take a deeper dive into the world of cryptography. The cornerstone of cryptography is the algorithm, or cipher. Cipher is just a fancy word for the series of steps that are taken for data to be encrypted or decrypted. In this video, we're going to look at several types of ciphers and how they work.

One of the first cipher types is the stream cipher. A stream cipher is a symmetric encryption method that encrypts 1 bit of plaintext at a time. This method is based on the one-time pad, or OTP, which was very popular during World War 2. OTP uses a symmetric encryption key that should be as long or even longer than the data being encrypted.
For example, if you had a small message that was only 15 bits long, a random 15-bit key would need to be generated. That key can then be used to encrypt your message using a process called Exclusive-ORing, or XORing. XORing means that we compare two strings, our message and our random key, to generate an output. We do this by lining them both up. If the bits match, a 0 is generated. If they don't match, a 1 is generated. The output is our ciphertext!
What makes this so interesting is that this demonstrates perfect secrecy. This means that, to a hacker, this ciphertext looks completely random. It would be just as difficult to brute-force the key as it would be to brute-force the data itself.
OTP only works properly if our secret key is only used once. If we use it more than once, a hacker could then start to decode the secret key. OTP works great if we're dealing with small messages. But what if we needed to encrypt every video in this course?
A video can range from 500 megabytes to up to 5 gigs or more. Since every video file would need to generate a key that's the same size or larger than the video, we would quickly end up running out of hard drive space. So with today's data types, the one-time pad just isn't very practical.
Stream ciphers offer a solution to this problem.
A stream cipher can use a smaller fixed-length key that can be used repeatedly throughout the encryption process. This key is called a seed key, and in our example we'll say that it's 2048 bits. This key is run through a pseudorandom number generator which outputs a new and unique encryption key called a keystream. Notice that this new key matches the size of our data. The keystream is then XORed with the data to give us our ciphertext.
While stream ciphers are less secure than the one-time pad, the advantage to this method is that it can be used in real time. One of the most widely used stream ciphers was RC4. But due to multiple vulnerabilities discovered, it's no longer in use.
Many symmetric encryption algorithms use the block cipher method. With block ciphers, instead of encrypting our data one bit at a time, the data is encrypted one chunk or block at a time. The common block sizes used are 64, 128, or 256 bits in length.
For example, let's say that we want to encrypt a file that's 800 bits in size. Using a 256-bit block size, the data will be encrypted 256 bits, or 32 bytes, at a time until the process is complete. Since the last block ends up being smaller than 256 bits, the algorithm pads the block with some random data to bring it up to 256 bits.
As shown here, there are several block cipher operation modes that can be utilized depending on the application or use. Let's talk about a few of them.
Electronic Code Book Mode, or ECB, is the simplest block cipher operation mode.
With this mode, each block of plaintext data is encrypted separately. Several blocks can be encrypted at the same time, allowing for faster encryption. The biggest disadvantage is that identical data results in the same ciphertext, meaning that a hacker would be able to decipher some of the data if they intercept multiple blocks.
Cipher Block Chaining is like ECB, except that it uses an initialization vector. The initialization vector is a starting variable that's XORed with the current block's plaintext to encrypt the data. The first initialization vector is a random string and

each subsequent initialization vector is the ciphertext from the previous block. CBC is more secure than ECB but slower because multiple blocks can't be encrypted at the same time.
Cipher Feedback Mode, or CFB, also utilizes an initialization vector. But instead of using it on the plaintext, the initialization vector is encrypted and then that result is XORed with the plaintext to create the ciphertext block. This is the equivalent of encrypting the plaintext with a one-time pad.
Output Feedback Mode, or OFB, is practically identical to Cipher Feedback Mode. The difference is the initialization vector used after the first round of encryption. The CFB's output is XORed with the plaintext and the result is the next block's initialization vector. The process is the same in Output Feedback Mode, except that the encryption's output is the next block's initialization vector before it's XORed with the plaintext.
Next we have Counter Mode. Similar to ECB, every encryption process in Counter Mode is separate. Instead of using an initialization vector, Counter Mode uses a nonce combined with an encrypted counter. Nonce is simply a fancy word for a random string that's used for all blocks. The nonce's encrypted output and counter are then XORed with the plaintext to create the ciphertext. The counter starts at 0 and increments every block. By combining the nonce and counter, each block is using a different value so that even if the data is the same, the output will be different.
If we want to provide authentication with confidentiality, we can use the Galois Counter Mode, or GCM. This mode works just like Counter Mode. First, we have the counter and nonce encrypted. The output is XOR-ed with the plaintext to give us the ciphertext. Here's where things get different. The ciphertext is combined with a special hash. That output contains the ciphertext along with a message authentication code that gives us assurance that the data hasn't been tampered with. Because this method is efficient and provides authentication, we see it used often with network communications such as wireless networks and web servers that use SSH or TLS.
The other block cipher modes are classified as unauthenticated encryption and GCM is classified as authenticated encryption. There are some other encryption methods that authenticate, but the most common one is the Galois Counter Mode.
We're putting more and more Internet of Things, or IoT, devices into our networks; the need to encrypt data has never been more important. In 2018, the National Institute of Standards and Technology, or NIST, began the process of standardizing encryption algorithms called lightweight cryptography for these types of devices.
Many IoT devices are small, low-powered devices that don't have the resources to handle the encryption methods we've covered. IoT devices have limitations such as only having a small amount of RAM and CPU power. Some devices even run on batteries. Lightweight cryptography algorithms must take this into account and still provide high levels of security while being efficient.
One huge risk with all encryption is that the data must first be decrypted before it can be used. Homomorphic encryption addresses this concern by allowing encrypted data to be used without decrypting it first. This is done by performing mathematical operations on the ciphertext instead of on the actual data itself. Homomorphic encryption works like other asymmetric encryption methods by using a public key to encrypt the data and a private key to decrypt it.
It helps to look at data as math problems to better understand the differences in the types of homomorphic encryption. There are three types of homomorphic encryption: Partially homomorphic, which allows for only simple mathematical operations like addition and subtraction to be performed; somewhat homomorphic, which allows for more complex math such as multiplication to occur but only for a limited number of times; and fully homomorphic, which can handle any mathematical operation an unlimited number of times. Homomorphic Encryption has the potential to be a game changer, but as of now it's incredibly slow and inefficient.
That's it for this lesson. In this lesson, we looked at the different ciphers used in cryptography. We first examined the stream cipher which encrypts data one bit at a time. Then we looked at how block ciphers work and the different operation modes. Finally, we looked at two newer forms of cryptography. Lightweight cryptography is being designed for IoT devices and homomorphic encryption allows data to be used without having to decrypt it.

3.1.6 Cryptography Algorithms Facts

The cornerstone of all cryptography is the algorithm or cipher. There are different types of ciphers in use today.

This lesson covers the following topics:

- Stream cipher
- Block cipher
- Lightweight cryptography
- Homomorphic encryption

Stream Cipher

A stream cipher is a symmetric encryption method that encrypts data one bit at a time. The stream cipher is based on the one-time pad (OTP) concept used extensively during World War 2. Consider the following OTP characteristics:

- The OTP uses a symmetric encryption key the same length as the data being encrypted.
- The encryption key is used to encrypt the data using a process called XORing. This means that two binary strings are compared. If the bits match, a zero is generated. If the bits do not match, a one is generated. The output of the XOR process is the ciphertext.
- The OTP demonstrates what is called perfect secrecy. This means that it is just as, if not more, difficult for a hacker to brute-force the key as it would be to brute-force the data itself.
- The OTP only provides perfect secrecy if the secret key is only used once. If used more than once, a hacker could begin to decode it.
- OTP works well when dealing with small messages, but it becomes impractical when dealing with large data due to the keys being so extensive.

A stream cipher solves the problem of having excessively large keys associated with OTP by using a smaller, fixed-length seed key, such as one that is 2048 bits in length. The following describes the process of creating a seed key:

1. The seed key is run through a pseudorandom number generator, which outputs a new and unique encryption key the same size as the data being encrypted. This new key is called a keystream.
2. The keystream is XORed with the data to create the ciphertext.
3. The seed key can be used repeatedly throughout the encryption process.

While stream ciphers are less secure than the one-time pad, this method can be used in real-time. One of the most widely used stream ciphers was Rivest's Cipher 4 (RC4). However, multiple vulnerabilities have been discovered in RC4, rendering it insecure. It is no longer used today.

Block Cipher

Many symmetric encryption algorithms use the block cipher method. Instead of encrypting our data one bit at a time, a block cipher encrypts the data one chunk at a time. Common block sizes are 64, 128, or 256 bits in length. For example, when encrypting a piece of data that is 100 bytes in size using a 256-bit block size, the data would be encrypted 32 bytes at a time (256 bits/8 = 32 bytes). Because the last block is less than 32 bytes, extra random bits are added to bring the block up to 32 bytes.

There are six block cipher modes of operation that can be utilized depending on the application or use:

Mode of Operation	Description
Electronic Code Book (ECB)	ECB is the simplest mode of operation. • Each block of plaintext data is encrypted separately. • Blocks of data can be encrypted simultaneously, allowing for faster encryption. • The biggest disadvantage is that blocks with identical data will generate the same ciphertext.
Cipher Block Chaining (CBC)	CBC is similar to ECB, except this mode uses an initialization vector (IV).

Mode of Operation	Description
	• The IV is a starting variable that is XORed with the plaintext of the current block to encrypt the data. • The IV for the starting block is a randomly generated value. Each subsequent IV is the ciphertext from the previous block. • CBC is more secure than ECB due to the IV, but it is slower because blocks cannot be encrypted simultaneously.
Cipher Feedback mode (CFB)	CFB also uses an IV, but instead of using it on the plaintext, the IV is encrypted first. That output is then XORed with the plaintext to create the block of ciphertext. • This is the equivalent of using a one-time pad to encrypt the data. • The IV for the starting block is a randomly generated value. Each subsequent IV is the ciphertext from the previous block.
Output Feedback mode (OFB)	This mode is identical to CFB except for the IV used after the first round. • The output of the IV encryption is used as the next block's ciphertext.
Counter mode (CTR)	Instead of using an initialization vector, CTR uses a nonce combined with a counter that is encrypted. • A nonce is a random string used for all blocks during the encryption process. • The encrypted output of the nonce and counter is then XORed with the plaintext to create the ciphertext. • The counter increments for each block. This ensures that each block uses a different value so that even if blocks have the same data, the ciphertext will be different.
Galois Counter mode (GCM)	All other modes of operation are unauthenticated forms of encryption. The Galois Counter mode provides both encryption and authentication. • GCM works like Counter mode, except the ciphertext is combined with a special hash. • The output of the ciphertext and hash contains the encrypted data and a Message Authentication Code (MAC) that gives assurance that the message has not been tampered with. • Because GCM is extremely efficient and provides authentication, it is often used with network communications such as 802.11 and when sending encrypted data to a web server using TLS or SSH. • There are other encryption methods that also provide authentication, but GCM is the most widely used method.

Lightweight Cryptography

In 2018, NIST began the process to standardize encryption algorithms called lightweight cryptography. Lightweight cryptography is meant to be used on Internet of Things (IoT) devices.

Many IoT devices are small, low-powered devices that do not have the resources to handle other encryption methods. Some of the limitations of IoT devices that lightweight cryptography needs to address are:

- Small amount of RAM
- Low CPU power
- Low-powered or runs on batteries

Lightweight cryptography algorithms need to work on these devices efficiently while still providing high levels of security.

Homomorphic Encryption

An inherent risk with all encryption is that for the data to be worked on (computation on ciphertexts), it must first be decrypted. Homomorphic encryption addresses this concern by allowing data to be worked on without decrypting it first.

There are three types of homomorphic encryption. To explain the differences, it works best to think of data as integers and to use math functions to represent the manipulation of that data.

Homomorphic Encryption Type	Description
Partially homomorphic encryption (PHE)	PHE allows only select simple math functions (such as addition) to be performed. This means that only one math function can be performed an unlimited number of times on the encrypted values.
Somewhat homomorphic encryption (SHE)	SHE allows more complex math (such as multiplication) to occur. However, it can only be performed a limited number of times.
Fully homomorphic encryption (FHE)	This method can handle both simple and advanced math functions (such as addition and multiplication) being performed an unlimited number of times on the encrypted values. FHE is still in the developmental stage.

3.1.7 Identify Cryptographic Modes of Operation

3.1.8 Blockchain (Lesson Video)

Transcript:

A blockchain is a unique and increasingly popular implementation of cryptography. Blockchain technology was developed in 2008 and really came to the public with the release of Bitcoin. It's a decentralized and distributed ledger that uses cryptography to keep data secure and records and verifies transactions between two parties. In this lesson, we'll look at how a blockchain works and some interesting implementations of this newer technology.

Bitcoin cryptocurrency is the first prevalent use of a blockchain.
The idea is to provide a way for people to make online transactions without the use of a centralized third party, such as a bank. Let's take a closer look at the blockchain and how it works.

Each block is a transaction that's stored in a public database, or the chain. The block contains information about the transaction, including time, date, parties involved, and a unique hash that separates it from other blocks on the chain.
Let's look at this blockchain in action.
Travis is purchasing something from Craig and needs to send him money. Using his personal secret key and Craig's public key, Travis requests the transaction, which is represented online as a block. The transaction is sent out on a peer-to-peer network that consists of a bunch of computers called nodes.
The network verifies the transaction using known algorithms. The transaction is added to the chain, which creates a permanent record that can't be altered or denied. Travis's ownership of the money now transfers to Craig. The entire transaction happens very quickly, usually within a matter of minutes.
What makes the blockchain so secure is that every node contains a copy of the ledger. If a hacker changes a transaction, it won't matter because a copy of the transaction is also on many other computers.
Not just anyone can join a blockchain network, however. Each node must prove themselves and actually do some work. This is done through a process called mining.
Mining is adding blocks to the chain. To do this, extremely complex math computations take place to generate a 64-digit hexadecimal hash. Creating it requires a lot of power and time, so the process is split between each node. As a reward for performing these tasks, the nodes are usually paid with cryptocurrency, like Bitcoin.
Even though each transaction is publicly visible, all personal information is encrypted and hidden from everyone, even the nodes. Because it's a shared ledger and every transaction is publicly available, all persons involved can be held accountable for their actions.
Sending money isn't the only way blockchain can be used. Some large companies, including Microsoft and IBM, are working to adapt different technologies to the blockchain.
Many transactions that currently rely on a paper-based system could benefit from blockchain. For example, car or house titles could be transferred over the blockchain. Because the transactions are transparent, this would create a clear picture of legal ownership.
We could also use the blockchain to track the movement of things like food from its origin to the market. Any product supply chain could be followed, and the fact that it's all transparent would allow everyone peace of mind because we could see every stop the product has made.
There are many other ways the blockchain could be used, and as the technology becomes more popular, we'll see the blockchain serve many functions.
That's it for this lesson. In this video, we discussed what a blockchain is and how it works. Then we looked at some implementations of blockchain technology.

3.1.9 Blockchain Facts

Blockchain is a unique and increasingly popular implementation of cryptography that was developed in 2008.

This lesson covers the following topics:

- Blockchain
- Blockchain transaction
- Blockchain implementations

Blockchain

Blockchain is a concept in which an expanding list of transactional records is secured using cryptography. Each record is referred to as a *block* and is run through a hash function. The hash value of the previous block in the chain is added to the hash calculation of the next block in the chain. This ensures that each successive block is cryptographically linked. Each block validates the hash of the previous block all the way through to the beginning of the chain, ensuring that each historical transaction has not been tampered with. In addition, each block typically includes a time stamp of one or more transactions as well as the data involved in the transactions themselves.

The blockchain is recorded in an **open public ledger** . This ledger does not exist as an individual file on a single computer; rather, one of the most important characteristics of a blockchain is that it is decentralized. The ledger is distributed across a peer-to-peer (P2P) network in order to mitigate the risks associated with having a single point of failure or compromise.

Blockchain users can, therefore, trust each other equally. Likewise, another defining quality of a blockchain is its openness—everyone has the same ability to view every transaction on a blockchain.

Blockchain technology has a variety of potential applications. It can ensure the integrity and transparency of financial transactions, legal contracts, copyright and intellectual property (IP) protection, online voting systems, identity management systems, and data storage.

The first big use of the blockchain was the cryptocurrency, Bitcoin. The purpose of Bitcoin is to provide a method for people to make online transactions without the use of a centralized third party such as a bank.

Blockchain Transaction

Each block contains information about the transaction, including:

- Time
- Date
- Parties involved
- A unique hash that separates the block from other blocks on the chain

Each block goes through the same process:

1. User1 requests a transaction with User2. The request is made using User1's personal secret key and User2's public key.
2. The transaction is represented online as a block.
3. The block is distributed to everyone on a peer-to-peer network.
4. The network users verify that the transaction is valid.
5. The block is added to the chain. This provides an indisputable and transparent record of the transaction.
6. The contents of the transaction move to User2.

The entire transaction happens very quickly, usually within a matter of minutes. Every node contains a copy of the ledger. If a hacker changed a transaction, it would not matter because a copy of the transaction is stored on many other computers.

Each node plays an important part in the blockchain. Each node must prove itself by performing work before being allowed to join the network. This is typically done through mining.

Mining is the process of adding blocks to the chain. Each block has a 64-digit hexadecimal hash generated by extremely complex math computations. Generating the hash requires a lot of time and computing power. The process is split between each node. As a reward for performing these computations, the nodes are usually paid with cryptocurrency, like Bitcoin.

Even though each transaction is publicly visible, all personal information is encrypted and hidden from everyone, even the nodes. Because it is a shared ledger and every transaction is publicly available, all persons involved can be held accountable for their actions.

Blockchain Implementations

Sending money is not the only way blockchain can be used. Some large companies, including Microsoft and IBM, are working to adapt different technologies to the blockchain.

Many transactions that currently rely on a paper-based system could benefit from blockchain. For example, a car or house title could be transferred over the blockchain. Because the transactions are transparent, this would create a clear picture of legal ownership.

A blockchain could be used to track the movement of a product, such as food. The ability to follow and see every stop the product has made on its way to the consumer would provide assurances of the product's safety.

3.1.10 Use Steganography to Hide a File (Demo Video)

Transcript:

Sometimes, in order to maintain access to a network or system, malicious users try to transfer files. In this demo, we'll discuss how to hide the contents of a file inside another file using a technique called steganography. People have used steganography to send secret messages for hundreds of years. Typically, this method is used when the sender is concerned that their traffic is being inspected by a third party.

We're going to use a free tool called OpenStego that's able to hide a file inside of an image. This tool is very easy to use and has a graphical user interface. We're going to run the tool on Linux, but it's also available on Windows.
When we open up the tool, the first thing we see is the Hide Data screen; since this is the screen we want, let's move on to the fields that need to be filled out. Message File is the name of the file we want to hide in the Cover File, and it will be saved to the Output Stego File. I already have a file I want to hide, so I'll select that now. I'll come over here and navigate down until I find my file, secret-information.txt. Let's click OK.
Now that we've selected the message file, we need to select the file we want to save the message into. I've already downloaded a picture, so we'll select it and then continue. Once again, I'll navigate to my Pictures folder, where I've stored the PNG we're going to use.
Lastly, we need to select where we would like to save the file that we've encoded information into. Let's just call it secret-forest.png and save it in the same folder. I'll click over here and enter in 'secret-forest.png'. We could enter a password here, but we'll just leave it for now. Since that's all the information we need, let's click Hide Data.
That's it! To see that it worked, let's check to see that the Secret Forest file has been created. I'll browse through my folders to get to the Pictures folder. This is the file we created that contains the hidden data. Let's take a look at the original file to see whether there are any major visual differences. This side-by-side comparison shows that, visually, the images appear to be identical. If we look at the file sizes, though, we can see a bit of a difference between the two. In the lower right-hand corner, you can see that the original image is 10 megabytes, and the file that we encoded data into is almost 12 megabytes. This kind of difference would be difficult to detect if you didn't know the size of the original file.
Now that we see that the new file has been created, we should make sure that the data was stored properly. Let's try to extract the data. Let's go back to OpenStego and click on the Extract Data button. This page is a bit simpler, since the program only needs the new file and a folder to save the extracted file. I'll provide that data now and attempt to extract the data. I'll come over here and select my file. Click OK. Next, we'll just save it in the Pictures folder and select the Extract Data button. We'll wait for a second while it processes.
You can see that a text file was created in the folder. The file has the same name as the file we originally stored in the image, since the steganography tool saves that information in the image as well. We should make sure that the data inside the file is actually correct by opening it. I'll come up here and open the text file. And here's all our secret passwords.
In this demo, we discussed steganography and methods for saving data to an image and extracting data from an image.

3.1.11 Hide Files with OpenStego (Simulation)

Scenario

You are the IT security administrator for a small corporate network. Recently, some of your firm's proprietary data leaked online. You have been asked to use steganography to encrypt data into a file to be shared with a business partner. The data will allow you to track the source if the information is leaked again.

In this lab, your task is to use OpenStego to hide data in photos as follows:

- Encrypt and password-protect the user data in the file to be shared.
    - Message file: **John.txt**

    - Cover file: **gear.png**
    - Output Sego file: **send.png** (saved in the Documents folder)
    - Password: **NoMor3L3@ks!**
- Confirm the functionality of the steganography by:
    - Extracting the data to **C:\Users\Administrator\Documents\Export** .
    - Open the extracted file to confirm that the associated username has been embedded into the file.

Explanation

Complete this lab as follows:

1. Encrypt the user data into the file to be shared.
    a. In the search field on the taskbar, type **OpenStego** .
    b. Under *Best match* , select **OpenStego** .
2. Select the Message, Cover, and Output Stego files.
    a. For the *Message File* field, select the **ellipses** [...] button at the end of the field.
    b. Double-click **John.txt** to select the file.
    c. For the *Cover File* field, select the **ellipses** [...] button at the end of the field.
    d. Double-click **gear.png** to select the file.
    e. For the *Output Stego File* field, select the **ellipses** [...] button at the end of the field.
    f. In the *File name* field, enter **send.png** and then select **Open** .
3. Password protect the file.
    a. In the *Password* field, enter **NoMor3L3@ks!**
    b. In the *Confirm Password* field, enter **NoMor3L3@ks!**
    c. Select **Hide Data** .
    d. Select **OK** .
4. Extract the data.
    a. Under *Data Hiding* , select **Extract Data** .
    b. For the *Input Stego File* field, select the **ellipses** [...] button.
    c. Double-click **send.png** to select the file with the encryption.
    d. For the *Output Folder for Message File* field, select the **ellipses** [...] button.
    e. Double-click **Export** to set it as the destination of the file output.
    f. Click **Select Folder** .
    g. In the *Password* field, enter **NoMor3L3@ks!** as the password.
    h. Select **Extract Data** .
    i. Select **OK** .
5. Verify that the decryption process was successful.
    a. From the taskbar, select **File Explorer** .
    b. Double-click **Documents** to navigate to the folder.
    c. Double-click **Export** to navigate to the folder.
    d. Double-click **John.txt** .

3.1.12 Cryptographic Attacks (Lesson Video)

Transcript:

No matter how many barriers we put in place to protect our data, hackers will always try to figure out a way to get around them and steal valuable information.

In this video, we're going to look at some common cryptographic attacks and what the future of cryptography might look like.

Encrypted data is usually secure, but there are no guarantees in the security world. By using new, targeted, or sophisticated attacks, hackers might be able to decrypt data you thought was safe. Some of the more common attacks are dictionary attacks, collision attacks, birthday attacks, and downgrade attacks.
A dictionary attack is a type of brute force attack that is used quite often. In this attack, the hacker has a huge list of words and phrases that are used to guess a decryption key. These attacks work well against weak passwords, such as password123. Using longer and uncommon passphrases is the key to beating dictionary attacks.
Another type of attack is the collision attack. A collision attack tries to find two inputs that produce the same hash value. This type of attack is often used on digital signatures.
For example, we have a hacker that creates two different documents that have an identical hash value. With this type of attach, the hacker wants to get Travis to accept the second document by making it seem that it came from Craig. The first document is sent to Craig, who agrees with what the document says, so he signs it and sends it back. The hacker then takes Craig's signature from that document, attaches it to a bad document, and sends that to Travis. Because the documents have the same hash, Travis' software is unable to detect that there's anything wrong, and it looks totally legitimate. The problem with this attack is the difficulty of generating two documents that have the same hash.
A birthday attack combines a collision attack and a brute force attack. This attack's name is taken from the birthday probability math problem.
If you have 30 people are in a room, the chance that someone has the same birthday as you is about 8 percent. But the probability that any two people in the room have the same birthday is 70 percent. This is because we're not looking for an exact match, just any match. This concept can be used to create two documents with the same hash, as in the collision attack example.
Another popular attack is the downgrade attack. Downgrade attacks force the system to use an older, less secure protocol for communication.
A common example of this attack is SSL exploitation. Many servers have both SSL and TLS installed on them. If a client can't use TLS, then the server can revert to SSL. A hacker can set up their computer to only use SSL, which will then allow them to launch SSL-based attacks on the server.
In this attack, the hacker intercepts the HTTPS packets and reverts them to HTTP packets. If the server isn't configured properly, it'll respond using HTTP, which allows the hacker to see everything being sent back and forth.
To combat these attacks, it's imperative that servers don't support older, less secure protocols. Proper server configuration is the key to stopping these types of attacks.
Now let's look ahead to what's coming in the security world. The future of computers and cryptography lies in quantum computing.
Classic computing works by processing bits, or 0s and 1s. These bits represent the electrical signals of on and off. Quantum computing uses qubits, which can exist as both a 1 and 0 at the same time. Quantum computing is so much more powerful than today's computing.
This increased computing power means that today's encryption standards can be hacked easily and quickly. An encryption key that might take years to crack with today's computers can take days or even hours with quantum computers.
To combat the inevitable increase of quantum computing, researchers have already started work on post-quantum cryptography. These new methods will be used to ensure the safety of our data.
That wraps up this lesson. In this video, we covered different types of cryptographic attacks, including dictionary, collision, birthday, and downgrade attacks. Then we looked at the future of cryptography, which involves quantum computing and post-quantum cryptography.

3.1.13 Cryptographic Attack Facts

Hackers attempt to figure out a way to get to data they want. Encrypting data is usually relatively secure, but there is, unfortunately, no such thing as a sure thing when it comes to protecting data. By using different types of attacks, hackers might be able to gain access to encrypted data.

This lesson covers the following topics:

- Common cryptographic attacks
- Future of cryptography

Common Cryptographic Attacks

The following table covers some of the more common cryptographic attacks.

Attack Method	Description
Dictionary	A dictionary attack is a type of brute-force attack. The hacker uses a list of words and phrases to try to guess the decryption key. • Dictionary attacks work well if weak passwords are used. • Using longer and uncommon passphrases is the best way to secure data against these attacks.
Collision attack	A collision attack tries to find two inputs that produce the same hash value. This type of attack is often used on digital signatures. • If a hacker wanted to get User2 to sign a document by making it seem like it came from User1, they would generate two documents that generate the same hash. • The hacker would send one document to User1 and get that signature. • The signature would be attached to the second document and sent to User2. Because the hashes are identical, User2 thinks the document is legitimate and has been signed by User1. Generating longer hash outputs is the key to stopping these types of attacks.
Birthday attack	This attack combines a collision attack and a brute-force attack. The name is taken from the birthday probability math problem. The birthday probability math problem states that if you have 30 people in a room, the probability that someone has the same birthday as you is approximately 8%. However, the probability that any two people in the room have the same birthday is 70%. This is because we are not looking for an exact match (just any match), so the probability is higher. Digital signatures can be susceptible to birthday attacks. Generating longer hash outputs is the key to stopping these attacks.
Downgrade attack	A downgrade attack forces the system to use an older, less secure communication protocol. • SSL exploitation is a common implementation of this attack. A hacker can set up their computer to only use SSL so that when the request is sent to the server, the server downgrades from TLS to SSL to communicate. This then allows the hacker to launch SSL-based attacks on the server. • Downgrade attacks are often used as part of a man-in-the-middle (MITM) attack. The hacker can intercept an HTTPS packet and downgrade it to an HTTP packet. If the server is not configured properly, the server responds using HTTP. This allows the hacker to now see all communications.

	To prevent downgrade attacks, servers must be set up not to support these older and less secure protocols. Proper server configuration is the key to stopping these types of attacks.

Future of Cryptography

The future of computers and cryptography lies in quantum computing. Classic computing works by processing bits of 1s and 0s. These bits represent electrical signals, on and off. Quantum computing uses qubits which can exist as both a 1 and 0 at the same time. Quantum computing is exponentially more powerful than today's computing standards.

This increased computing power means that today's encryption standards can be hacked easily and quickly. An encryption key that might take years to crack with today's computers can take days or even hours with quantum computers. To combat the inevitable increase of quantum computing, researchers have already started work on post-quantum cryptography. These new methods will be used to ensure the safety of our data in the future.

3.1.14 Practice Questions (Section Quiz)

q_cryp_concepts_algorithms_secp8

You are a cybersecurity analyst at a large corporation. The company has recently received a series of suspicious emails containing encrypted messages.

You suspect that the messages are using a combination of substitution and transposition algorithms for encryption.

The most recent message reads: "HLOOLELWRD".

Which of the following steps would you take to decrypt this message?

Answers:

- Apply a Caesar cipher with a shift of 3 to the right.
- Apply a ROT13 substitution cipher.
- ***Rearrange the letters in blocks of two.**
- Apply a Caesar cipher with a shift of 3 to the left.

Explanation:

Rearrange the letters in blocks of two is the correct answer. The message appears to be encrypted using a simple columnar transposition cipher, where letters are written in columns and then concatenated in rows. Rearranging the letters in blocks of two (i.e., treating "HL", "OO", "LE", "LW", "RD" as separate blocks) would result in the plaintext message "HELLO WORLD".

Apply a Caesar cipher with a shift of 3 to the right is incorrect. A Caesar cipher is a type of substitution cipher, not a transposition cipher. Applying a Caesar cipher to this message would not result in a meaningful decryption.

Apply a ROT13 substitution cipher is incorrect. ROT13 is a specific type of Caesar cipher that shifts letters 13 places. However, this does not account for the transposition aspect of the encryption.

Apply a Caesar cipher with a shift of 3 to the left is incorrect. A Caesar cipher is a type of substitution cipher and would not account for the transposition aspect of the encryption.

q_cryp_concepts_caesar_cipher_secp8

Which of the following encryption methods works by shifting each letter in the alphabet a certain number of spaces to the right or left?

Answers:

- ***Caesar cipher**
- Encryption key
- Hashing
- Salt

Explanation:

One of the more popular forms of encryption is the Caesar cipher. This encryption method works be shifting each letter in the alphabet a certain number of spaces to the right or left. An example of this cipher is shifting to the right by three letters: A becomes D, B becomes E, C becomes F, and so forth.

Encryption keys are used to encrypt and decrypt data. The key is a string of bits that is randomly generated using a specific cipher, such as Advanced Encryption Standard (AES). There are two types of encryption methods used with keys: symmetric and asymmetric.

Hashing is the process of converting one value into another using a mathematical algorithm like MD5 or SHA. This fixed length of data is called the hash.

Salt, or salting the hash, means that a random number of characters are added to a password before the hash is created.

q_cryp_concepts_ecc_secp8

You are creating a website for a financial investment company customers and are using a cryptography method that secures connections and data transmissions by generating smaller keys that are more secure than most other methods.

Which of the following cryptography methods are you using?

Answers:

- ***Elliptic Curve Cryptography (ECC)**
- Perfect Forward Secrecy
- Steganography
- Digital signature

Explanation:

You are using Elliptic Curve Cryptography (ECC). ECC is one of the newer methods being implemented. It is able to generate smaller keys that are more secure than most other methods. Many websites today use ECC to secure connections and data transmissions.

The Perfect Forward Secrecy cryptography method is used quite often in messaging apps. Instead of the same key being used for an entire conversation or session on a website, each transmission is encrypted with a different unique key.

Steganography is the technique of hiding or concealing a file, message, image, or video within another file, message, image, or video. Special programs are often used to hide messages in media files. If a hacker intercepts the message, all they see is the media. They don't know that there is a hidden message.

By combining a user's private encryption key and a hash of the data, a user can create a digital signature. A digital signature verifies that the data is legitimate and provides non-repudiation. This means that the sender cannot deny having sent the file.

q_cryp_concepts_hashing_secp8

Hashing is the process of converting one value into another using a mathematical algorithm like MD5 or SHA. This fixed length of data is called the hash.

Which of the following are true statements about hashing? (Select two.)

Answers:

- ***Hashing is used on data that does not need to be decrypted, such as a password.**
- ***A hash cannot be decrypted.**
- A hash is a string of bits that is randomly generated using a specific cipher.
- Hashing works by shifting each letter in the alphabet a certain number of spaces to the right or left.
- A hash verifies that the data is legitimate and provides non-repudiation.

Explanation:

The following are true statements about hashing:

- Hashing is used on data that does not need to be decrypted, such as a password.
- A hash cannot be decrypted.
- When a piece of data is run through a hashing algorithm, it always generates the same hash.

An encryption key is a string of bits that is randomly generated using a specific cipher, such as Advanced Encryption Standard (AES).

A Caesar cipher works be shifting each letter in the alphabet a certain number of spaces to the right or left.

A digital signature verifies that the data is legitimate and provides non-repudiation. This means that the sender cannot deny having sent the file.

q_cryp_concepts_stegano_secp8

Which of the following terms means a cryptography mechanism that hides secret communications within various forms of data?

Answers:

- Cryptanalysis
- ***Steganography**
- Algorithm
- Ciphertext

Explanation:

Steganography is the cryptography mechanism that hides secret communications within various forms of data.

Ciphertext is the encrypted form of a message that makes it unreadable to all but those the message is intended for.

Cryptanalysis is the method of recovering original data that has been encrypted without having access to the key used in the encryption process.

A cipher or algorithm is the process or formula used to convert a message or otherwise hide its meaning.

q_asys_sys_encrypt_asym_01_secp8

How many keys are used with asymmetric (public key) cryptography?

Answers:

- One
- ***Two**
- Three
- Four

Explanation:

Public key (asymmetric) cryptography uses two keys. One key is referred to as the public key and the other as the private key. This key pair overcomes the difficulties associated with the secure distribution of private keys. The communicating parties do not need to share secret information, as only the public keys are shared. Public keys are associated with users through authentication, usually through a mutually trusted directory, such as a certificate authority. The sender transmits a confidential message using only the recipient's public key. The message can only be decrypted with the associated private key possessed solely by the recipient. Public key cryptography not only provides encryption but is the basis for authentication technologies such as digital signatures.

q_asys_sys_encrypt_asym_02_secp8

Which of the following algorithms are used in asymmetric encryption? (Select two.)

Answers:

- ***RSA**
- Twofish
- AES
- ***Diffie-Hellman**
- Blowfish

Explanation:

RSA and Diffie-Hellman are asymmetric algorithms. RSA, one of the earliest encryption algorithms, can also be used for digital signatures. The Diffie-Hellman Protocol was created in 1976 but is still in use today in technologies such as SSL, SSH, and IPsec.

AES is the most the most commonly-used symmetric (not asymmetric) cipher.

Twofish is a symmetric encryption algorithm that uses a single key to both encrypt and decrypt data and information.

Blowfish is a variable-length, symmetric, 64-bit block cipher.

q_asys_sys_encrypt_asym_03_secp8

A systems administrator for a large organization dealing with massive amounts of data must ensure the security of data stored on disks and during transfers over the network.

Recently, the organization has encountered challenges with encrypting and decrypting large volumes of data.

Which encryption method would be inefficient for encrypting a large amount of data on a disk or transporting it over a network?

Answers:

- ***Asymmetric encryption**
- Symmetric encryption
- Hybrid encryption
- Obfuscation techniques

Explanation:

While asymmetric encryption offers advantages in certain areas, it becomes inefficient when dealing with large volumes of data on disks or during network transport due to its computational overhead.

Asymmetric encryption requires more processing power and time when compared to symmetric encryption, which is more efficient for bulk data encryption.

Hybrid encryption combines the benefits of both asymmetric and symmetric encryption but does not alleviate the inefficiencies of asymmetric encryption for large data encryption.

Obfuscation techniques are not encryption methods and would not address the performance challenges associated with encrypting large amounts of data. Obfuscation involves making a message or data difficult to find, such as hiding messages in files.

q_asys_sys_encrypt_ephemeral_keys_secp8

Which of the following statements about ephemeral keys is true?

Answers:

- Ephemeral keys are long-term keys used for multiple sessions.
- Ephemeral keys are used to provide integrity, but not confidentiality.
- Ephemeral keys are used in symmetric encryption only.
- ***Ephemeral keys are temporary and used for a single session only.**

Explanation:

Ephemeral keys are temporary keys used for a single session only. They are generated for each session and discarded after use, which provides an additional layer of security and perfect secrecy.

Ephemeral keys are not long-term keys; they are temporary and used for a single session only.

Ephemeral keys are used to provide both integrity and confidentiality. They ensure that the session's encryption key cannot be discovered even if the long-term private key is compromised.

Ephemeral keys can be used in both symmetric and asymmetric encryption. In asymmetric encryption, they are often used in combination with long-term keys to provide perfect forward secrecy.

q_asys_sys_encrypt_hash_secp8

A receiver wants to verify the integrity of a message received from a sender. A hashing value is contained within the digital signature of the sender.

Which of the following must the receiver use to access the hashing value and verify the integrity of the transmission?

Answers:

- Receiver's private key
- Receiver's public key
- Sender's private key
- ***Sender's public key**

Explanation:

Digital signatures are created using the sender's private key. Therefore, only the sender's public key can be used to verify and open any data encrypted with the sender's private key.

The recipient's private and public keys are not involved in this type of cryptography situation. Often, the hashing value of a message is protected by the sender's private key (their digital signature). The recipient must extract the original hashing value.

q_asys_sys_encrypt_hybrid_crypto_secp8

Which of the following statements about hybrid cryptosystems is true?

Answers:

- Hybrid cryptosystems use only symmetric encryption for both key exchange and data transmission.
- In hybrid cryptosystems, the symmetric key is used to encrypt the public key.
- Hybrid cryptosystems use the same key for both encryption and decryption processes.
- ***In hybrid cryptosystems, the public key is used to encrypt the symmetric key which is then used for data encryption.**

Explanation:

In hybrid cryptosystems, the public key is used to encrypt the symmetric key. This encrypted symmetric key is then sent to the receiver who uses their private key to decrypt it. The decrypted symmetric key is then used for data encryption and decryption.

Hybrid cryptosystems use asymmetric encryption for key exchange and symmetric encryption for data transmission.

In hybrid cryptosystems, the public key is used to encrypt the symmetric key, not the other way around.

While it's true that symmetric encryption uses the same key for encryption and decryption, hybrid cryptosystems also involve asymmetric encryption which uses different keys for encryption and decryption.

q_asys_sys_encrypt_key_01_secp8

Mary wants to send a message to Sam in such a way that only Sam can read it.

Which key should be used to encrypt the message?

Answers:

- ***Sam's public key**
- Sam's private key
- Mary's public key
- Mary's private key

Explanation:

Sam's public key should be used to encrypt the message. Only the corresponding private key, which only Sam has, can be used to decrypt the message.

Mary cannot use Sam's private key because only Sam has that key. Anything encrypted with the private key can be decrypted by anyone with the public key.

Encrypting the message using Mary's private key would mean that anyone could read the data using Mary's public key. Encrypting with Mary's public key would mean that only Mary would be able to decrypt it using her private key.

q_asys_sys_encrypt_key_02_secp8

Mary wants to send a message to Sam. She wants to digitally sign the message to prove that she sent it.

Which key would Mary use to create the digital signature?

Answers:

- Sam's public key
- Sam's private key
- Her public key
- ***Her private key**

Explanation:

Mary should use her private key to create the digital signature. This proves that only Mary could have sent the message because only Mary has access to her private key. Sam would use Mary's public key to verify the digital signature.

Use Sam's public key to encrypt a message that only Sam should be able to read. Only the corresponding private key, which only Sam has, can be used to decrypt the message.

Mary cannot use Sam's private key because only Sam has that key. Anything encrypted with the private key can be decrypted by anyone with the public key. Encrypting the message with Mary's public key would mean that only Mary would be able to decrypt it using her private key. But she could not prove where the message came from because anyone has access to Mary's public key.

q_asys_sys_encrypt_key_03_secp8

Which type(s) of key(s) are used in symmetric cryptography?

Answers:

- Two unique sets of key pairs
- A single key pair
- ***A shared key**
- A unique key for each participant

Explanation:

Symmetric cryptography uses a shared key. Both communication partners must be in possession of the same key in order to exchanged encrypted data.

Asymmetric cryptography uses a unique key pair for each participant. This key pair consists of a public key and a private key.

q_asys_sys_encrypt_key_04_secp8

How many keys are used with symmetric key cryptography?

Answers:

- ***One**
- Two
- Four
- Five

Explanation:

Private key, or symmetric, cryptography uses a single shared key. Both communicating parties must possess the shared key to encrypt and decrypt messages. The biggest challenge to symmetric cryptography is the constant need to protect the shared private key. This protection must be applied at all times, including during the initial transmission of the shared key between the parties.

q_asys_sys_encrypt_secret_01_secp8

Above all else, what must be protected to maintain the security and benefit of an asymmetric cryptographic solution, especially if it is widely used for digital certificates?

Answers:

- ***Private keys**
- Public keys
- Cryptographic algorithm
- Hash values

Explanation:

The strength of an asymmetric cryptographic system lies in the secrecy and security of its private keys. A digital certificate and a digital signature are little more than unique applications of a private key. If the private keys are compromised for a single user, for a secured network, or for a digital certificate authority, the entire realm of trust is destroyed.

The public key cannot be used to decrypt ciphertext (only the private key), and is less important that the private key.

Asymmetric encryption can be implemented using a number of cryptographic algorithms. However, no matter what algorithm is being used, without the private key the data cannot be decrypted.

Hash values are part of the process of using hashing algorithms. However, as with cryptographic algorithms, without the private key the encrypted data cannot be decrypted.

q_asys_sys_encrypt_secret_02_secp8

The success of asymmetric encryption is MOST dependent upon which of the following?

Answers:

- The integrity of the individuals who created the cryptosystem
- The secrecy of the algorithm
- The complexity of the ciphertext
- ***The secrecy of the key**

Explanation:

The strength of an asymmetric encryption system lies in the secrecy and security of its private keys.

While it's important to trust those who create a cryptosystem, if you are using a cryptosystem it is probably because it has already been recognized as a trusted system by the industry and other companies.

The strength of a cryptosystem should not be in the secrecy of the algorithm. This means that the algorithm is usually published and can be scrutinized for weaknesses.

No matter how complex the algorithm, if the private keys are not kept secure, the encrypted data is at risk.

q_asys_sys_encrypt_sym_01_secp8

Which of the following algorithms are used in symmetric encryption? (Select two.)

Answers:

- ***DES**
- RSA
- ***Blowfish**
- Diffie-Hellman
- ECC

Explanation:

DES and Blowfish are symmetric encryption algorithms.

RSA, Diffie-Hellman, and ECC are asymmetric encryption algorithms.

q_asys_sys_encrypt_sym_02_secp8

If a message sender encrypts a message with a key and a message receiver decrypts it using the same key, which type of key exchange is taking place?

Answers:

- ***Symmetric**
- Asymmetric
- Digital signature
- Counter mode

Explanation:

A symmetric key is when the sender uses a public key to encrypt a message and the recipient uses that same public key to decrypt it.

An asymmetric key is where the sender's and receiver's keys are both different for the encryption and decryption processes.

Using counter mode, both the sender and recipient access a reliable counter that computes a new shared value each time a ciphertext block is exchanged.

A digital signature is a mathematical scheme for demonstrating the authenticity of digital message or document.

q_asys_sys_encrypt_sym_03_secp8

A newly launched online store wants to secure transactions between the store and customers. The store must guarantee the authenticity of transactions, provide confidentiality, and ensure that only authorized recipients can access the purchase details.

Which cryptographic technique would best meet these requirements?

Answers:

- Symmetric encryption
- Hashing techniques
- ***Asymmetric encryption**
- Hybrid encryption

Explanation:

Asymmetric encryption uses a pair of keys - • public and private. The online store can encrypt the transaction details with the customer's public key, ensuring that only the customer, who holds the corresponding private key, can decrypt and access the details.

Symmetric encryption provides confidentiality fails to inherently provide authentication or non-repudiation, as the same key is for both encryption and decryption.

Hashing techniques verify the integrity of the data, but they do not provide encryption or the capability to validate the sender's authenticity.

While hybrid encryption provides the benefits of both symmetric and asymmetric encryption, it is more complex and allows for secure key exchange and efficient data encryption.

q_asys_sys_encrypt_weak_01_secp8

Which of the following encryption mechanisms offers the least security because of weak keys?

Answers:

- AES
- TwoFish
- IDEA
- ***DES**

Explanation:

DES offers the least encryption security of all the cryptography systems in this list. DES has a limitation of 56-bit keys, the weakest of those listed here. The strength of a cryptosystem lies not only in long keys but in the algorithm, initialization vector or method, the proper use of the keyspace, and the protection and management of keys.

AES (128-, 192-, and 256-bit keys), TwoFish (up to 256-bit keys), and IDEA (128-bit keys) all support stronger keys than DES.

q_asys_sys_encrypt_weak_02_secp8

Which of the following is the weakest symmetric encryption method?

Answers:

- ***DES**
- AES
- 3DES
- Twofish
- Blowfish

Explanation:

DES was one of the first symmetric encryption methods and is now obsolete (known weaknesses can be used to break the encryption).

3DES improves upon DES by applying the encryption three times. It is an acceptable alternative to DES. AES is stronger and faster than 3DES when implemented with a large key size (256 bits).

Blowfish and Twofish were alternatives to DES, but AES was chosen to replace DES.

q_cryp_algorithm_ctr_secp8

There are several block cipher modes of operation that can be utilized depending on the application or use.

Which of the following block cipher modes of operation uses a nonce combined with a counter that is encrypted?

Answers:

- ***Counter Mode (CTR)**
- Cipher Block Chaining (CBC)
- Cipher Feedback Mode (CFB)
- Electronic Code Book (ECB)

Explanation:

Instead of using an initialization vector, CTR uses a nonce combined with a counter that is encrypted. A nonce is a random string that is used for all blocks during the encryption process. The encrypted output of the nonce and counter is then XORed with the plaintext to create the ciphertext.

Cipher Block Chaining (CBC) uses an initialization vector (IV). The IV is a starting variable that is XORed with the plaintext of the current block to encrypt the data.

Cipher Feedback Mode (CFB) also uses an IV, but instead of using it on the plaintext, the IV is encrypted first. That output is then XORed with the plaintext to create the block of ciphertext.

Electronic Code Book (ECB) is the simplest mode of operation. Each block of plaintext data is encrypted separately. Blocks of data can be encrypted simultaneously allowing for faster encryption.

q_cryp_algorithm_gcm_secp8

Which of the following block cipher modes of operation provides both encryption and authentication?

Answers:

- ***Galois Counter Mode (GCM)**
- Cipher Block Chaining (CBC)
- Cipher Feedback Mode (CFB)
- Electronic Code Book (ECB)

Explanation:

The Galois Counter Mode (GCM) provides both encryption and authentication. All other block cipher modes of operation are unauthenticated forms of encryption.

Cipher Block Chaining (CBC) uses an initialization vector (IV). The IV is a starting variable that is XORed with the plaintext of the current block to encrypt the data.

Cipher Feedback Mode (CFB) also uses an IV, but instead of using it on the plaintext, the IV is encrypted first. That output is then XORed with the plaintext to create the block of ciphertext.

Electronic Code Book (ECB) is the simplest mode of operation. Each block of plaintext data is encrypted separately. Blocks of data can be encrypted simultaneously allowing for faster encryption.

q_cryp_algorithm_homomorphic_secp8

Which of the following types of encryption is specifically designed to allow data to be worked on without decrypting it first?

Answers:

- Lightweight cryptography
- ***Homomorphic encryption**
- Block cipher
- Stream cipher

Explanation:

An inherent risk with all encryption is that for the data to be worked on (computation on ciphertexts), it must first be decrypted. Homomorphic encryption addresses this concern by allowing data to be worked on without decrypting it first.

In 2018, NIST began the process to standardize encryption algorithms called lightweight cryptography. Lightweight cryptography is meant to be used on Internet of Things (IoT) devices.

Many symmetric encryption algorithms use the block cipher method. Instead of encrypting our data one bit at a time, a block cipher encrypts the data one chunk at a time.

A stream cipher is a symmetric encryption method that encrypts data one bit at a time. The stream cipher is based on the one-time pad (OTP) concept, which was used extensively during World War 2.

q_cryp_algorithm_lightweight_secp8

Which of the following types of encryption is specifically designed to be used on Internet of Things (IoT) devices?

Answers:

- ***Lightweight cryptography**
- Homomorphic encryption
- Block cipher
- Stream cipher

Explanation:

In 2018, NIST began the process to standardize encryption algorithms called lightweight cryptography. Lightweight cryptography is meant to be used on Internet of Things (IoT) devices.

An inherent risk with all encryption is that for the data to be worked on (computation on ciphertexts), it must first be decrypted. Homomorphic encryption addresses this concern by allowing data to be worked on without decrypting it first.

Many symmetric encryption algorithms use the block cipher method. Instead of encrypting our data one bit at a time, a block cipher encrypts the data one chunk at a time.

A stream cipher is a symmetric encryption method that encrypts data one bit at a time. The stream cipher is based on the one-time pad (OTP) concept, which was used extensively during World War 2.

q_cryp_algorithm_otp_secp8

Which of the following are true concerning the one-time pad (OTP) concept on which a streaming cipher is based? (Select two.)

Answers:

- ***OTP uses a symmetric encryption key that is the same length as the data being encrypted.**
- OTP encrypts the data one chunk at a time.
- ***OTP demonstrates what is called perfect secrecy.**
- OTP is meant to be used on Internet of Things (IoT) devices.
- OTP allows data to be worked on without decrypting it first.

Explanation:

The following is true concerning the OTP concept:

- OTP uses a symmetric encryption key that is the same length as the data being encrypted.
- OTP demonstrates what is called perfect secrecy.
- The encryption key is used to encrypt the data using a process called XORing.
- OTP only provides perfect secrecy if the secret key is only used once.
- OTP works well when dealing with small messages, but it becomes impractical when dealing with large data due to the keys being so extensive.

A block cipher encrypts data one chunk at a time.

Lightweight cryptography is meant to be used on Internet of Things (IoT) devices.

Homomorphic encryption allows data to be worked on without decrypting it first.

q_blockchain_business_processes_secp8

A company's leadership team has decided to integrate blockchain technology into its business processes to increase security, transparency, and efficiency. They have consulted a team of IT professionals to develop a secure communication infrastructure that supports their blockchain initiative.

When developing a robust and secure communication infrastructure for the implementation of blockchain technology, what factors should the IT professionals consider to maintain the integrity of the open public ledger and ensure the secure exchange of data across the network? (Select two.)

Answers:

- ***Implementing secure, encrypted communication protocols.**
- ***Ensuring the public ledger is accessible and transparent to all network members.**
- Restricting access to the public ledger to senior management only.
- Setting up data obfuscation techniques for the ledger entries.
- Ensuring that each transaction is securely stored on only one computer.

Explanation:

In a blockchain network, it is crucial to have

- Secure, encrypted communication protocols to maintain data integrity during transport.
- Transparency to keep the open public ledger accountable to all network members.

The public ledger in a blockchain system should be transparent to all members of the network, not only to the senior management.

While obfuscation can be a method to protect code, it does not typically get used within the entries of a blockchain's public ledger, which relies on transparency and validation across the network.

Every node in a blockchain contains a copy of the ledger. If a hacker changed a transaction, it wouldn't matter because a copy of the transaction is stored on many other computers.

q_blockchain_process_bitcoin_secp8

Which of the following was the first big use of blockchain cryptography process?

Answers:

- ***Cryptocurrency**
- Contracts
- Records
- Food

Explanation:

While the blockchain cryptography method can be used for items such as tracking contracts, records, and food products, the first big use of the blockchain was the Bitcoin cryptocurrency.

q_blockchain_process_steps_secp8

Blockchain is a unique and increasingly popular implementation of cryptography. A blockchain is a decentralized and distributed ledger that records and verifies transactions between two parties.

The list on the left describes each step a block goes through as part of the blockchain cryptographic process.

From the list on the left, drag a description to its proper step order on the right.

Answers:

- User1 requests a transaction with User2.
- The block is added to the chain.
- The network users verify the transaction is valid.
- The transaction is represented online as a block.
- The contents of the transaction move to User2.
- The block is distributed to everyone on a peer-to-peer network.

Explanation:

The following (in order) are the steps each block goes through as part of the blockchain cryptographic process:

1. User1 requests a transaction with User2. The request is made using User1's personal secret key and User2's public key.
2. The transaction is represented online as a block.
3. The block is distributed to everyone on a peer-to-peer network.
4. The network users verify the transaction is valid.
5. The block is added to the chain. This provides a indisputable and transparent record of the transaction.
6. The contents of the transaction move to User2.

q_cryp_attacks_collision_secp8

An incident response team detected a threat actor attempting to find two different inputs that produce the same hash value in the company's secure communication system.

Which of the following BEST describes this type of attack?

Answers:

- ***Collision attack**

- Birthday attack
- Brute-force attack
- Side-channel attack

Explanation:

In a collision attack, an attacker tries to find two different inputs that produce the same hash value.

Birthday attacks focus on the probability that two users will have the same hashed value, as opposed to deliberately trying to find two different inputs producing the same hash.

Brute-force attacks can apply in cryptographic systems but do not involve finding two different inputs that produce the same hash value.

Side-channel attacks are techniques used to extract secret cryptographic keys from a system by analyzing physical information leakage, such as time to execute cryptographic algorithms, power consumption, or even sound. They do not necessarily pertain to creating hash collisions.

q_cryp_attacks_dictionary_secp8

Which type of password attack employs a list of pre-defined passwords that it tries against a login prompt?

Answers:

- Collision attack
- Birthday attack
- ***Dictionary attack**
- Downgrade attack

Explanation:

A dictionary attack is a type of brute-force attack. A hacker uses a list of words and phrases to try to guess the decryption key.

- Dictionary attacks work well if weak passwords are used.
- Using longer and uncommon passphrases is the best way to secure data against these attacks.

A collision attack tries to find two inputs that produce the same hash value. This type of attack is often used on digital signatures.

A birthday attack combines a collision attack and brute-force attack. The name is taken from the birthday probability math problem.

A downgrade attack forces the system to use an older, less secure communication protocol.

q_cryp_attacks_downgrade_secp8

Which of the following cryptographic attacks uses SSL exploitation as a common implementation of this attack?

Answers:

- ***Downgrade attack**
- Birthday attack

- Collision attack
- Dictionary attack

Explanation:

A downgrade attack forces the system to use an older, less secure communication protocol. SSL exploitation is a common implementation of this type of attack.

A birthday attack combines a collision attack and brute-force attack. The name is taken from the birthday probability math problem.

A collision attack tries to find two inputs that produce the same hash value. This type of attack is often used on digital signatures.

A dictionary attack is a type of brute-force attack. The hacker uses a list of words and phrases to try to guess the decryption key.

q_cryp_attacks_quantum_computing_secp8

What is the key difference between classical computing and quantum computing that makes quantum computing exponentially more powerful?

Answers:

- Quantum computers use electricity, while classical computers do not.
- Quantum computers use bits, while classical computers use qubits.
- ***Quantum computers can process multiple possibilities simultaneously, while classical computers cannot.**
- Quantum computers are smaller than classical computers.

Explanation:

Quantum computers can process multiple possibilities simultaneously, while classical computers cannot is correct. Quantum computers use qubits, which can exist as both a 1 and 0 at the same time. This allows quantum computers to process multiple possibilities simultaneously, making them exponentially more powerful than classical computers.

Both quantum and classical computers use electricity. The difference lies in the way they process information.

Classical computers use bits (binary digits) that can be either a 0 or a 1. Quantum computers use qubits, which can exist in multiple states at once.

The size of a computer does not determine its computational power. Quantum computers can be larger, smaller, or the same size as classical computers.

3.2 Cryptography Implementations

As you study this section, answer the following questions:

- How can cryptography support the goals of information security?
- What cryptographic information is stored in a digital certificate?
- Why is reusing encryption keys considered a weakness?
- What are the potential consequences if a company loses control of a private key?

- What mechanism informs clients about suspended or revoked keys?
- What functionality does a Trusted Platform Module (TPM) chip provide?

In this section, you will learn to:

- Verify a device for TPM.

The key terms for this section include:

Term	Definition
Obfuscation	A technique that essentially hides or camouflages code or other information so that it is harder to read by unauthorized users.
Steganography	A technique for obscuring the presence of a message, often by embedding information within a file or other entity.
Data masking	A de-identification method where generic or placeholder labels are substituted for real data while preserving the structure or format of the original data.
Tokenization	A de-identification method where a unique token is substituted for real data.
Key management system	In public key infrastructure (PKI), procedures and tools that centralizes generation and storage of cryptographic keys.
Trusted Platform Module (TPM)	Specification for secure hardware-based storage of encryption keys, hashed passwords, and other user- and platform-identification information.
Application programming interface (API)	Methods exposed by a script or program that allow other scripts or programs to use it. For example, an API enables software developers to access functions of the TCP/IP network stack under a particular operating system.
Secure enclave	CPU extensions that protect data stored in system memory so that an untrusted process cannot read it.

This section helps you prepare for the following certification exam objectives:

Exam	Objective
CompTIA Security+ SY0-701	1.4 Explain the importance of using appropriate cryptographic solutions. • Encryption ○ Level

	▪ Full-disk ○ Asymmetric ○ Symmetric ○ Key exchange • Tools ○ Trusted Platform Module (TPM) ○ Hardware security module (HSM) ○ Key management system ○ Secure enclave • Obfuscation ○ Steganography ○ Hashing • Digital signatures
TestOut Security Pro	4.0 Data Security 4.2 Implement Encryption Technologies 4.2.1 Encrypt data communications 4.2.2 Encrypt files

3.2.1 Combining Cryptographic Methods (Lesson Video)

Transcript:

Using cryptography lets you secure your data against unauthorized users, but in some cases, it's beneficial if you combine different cryptographic methods to increase data security.

In this video, we'll look at hybrid models, digital signatures, and combining encryption with steganography.
Hybrid cryptographic models combine the use of symmetric and asymmetric keys to encrypt data.
Asymmetric encryption methods provide an easier way to exchange keys safely, but are not very efficient because they rely on some complicated mathematical computations. Symmetric encryptions are efficient, but because it can be a pain to get the keys out, they're not very convenient. A hybrid cryptosystem combines the convenience of asymmetric methods and the efficiency of symmetric methods.
One example of this combination is the Microsoft Encrypting File System, or EFS. EFS was introduced in version 3.0 of NTFS. It has been included in every version of Windows except Home edition since Windows 2000.
EFS works by encrypting a file with a special symmetric key called the File Encryption Key, or FEK. The user's public asymmetric key is then used to encrypt the FEK.
During decryption, the user's private key is used to decrypt the FEK, which is then used to decrypt the file.
By combining the security of the symmetric keys and the convenience of the asymmetric keys, Microsoft has made it easy for users to encrypt their data. The main drawback of EFS is that the user's private key is essentially their password. This means that the encryption is only as strong as the user's password.
One very common practice that combines cryptographic methods
is the digital signature. A digital signature combines the hash of a file and a user's private key to electronically sign a document, providing an authentic and non-repudiation file.
For example, if we had a large file that needed to be digitally signed, we could use asymmetric encryption to simply encrypt it. However, that process is slow and could generate a very large file size. Instead, we can create a hash of the file.
The three main hashing algorithms used today are SHA-1, which generates a 128-bit key, MD5, which generates a 160-bit key, and SHA-2, which is also commonly referred to as SHA-256. It creates a 256-bit key.
Whichever algorithm is used, the hash generates a fingerprint of the file. Now, instead of encrypting the file itself, we can encrypt the hash that was generated using our private key. We combine that encrypted hash with the file to digitally sign it.

Now, when we send the message to the recipient, she'll first generate a hash of the file. She'll then use our public key to decrypt the hash that we generated and compare it with theirs. If the hashes match, then they can be assured that the message is legitimate and hasn't been altered.
We can take this one step further and encrypt the file itself along with the digital signature using a digital envelope. To do this, we would use the recipient's public key to encrypt the data. The ciphertext, hash, and digital signature are all combined and sent together. The recipient uses our public key to decrypt the hash to authenticate the message. Then they use their private key to decrypt the ciphertext.
By combining the digital signature with asymmetric encryption, we get authentication, confidentiality, integrity, and non-repudiation.
An interesting combination of cryptographic methods is using asymmetric encryption with steganography. There's been a fairly large amount of recent research on ways to combine these methods effectively.
Let's look at how this would work.
We start by encrypting our plaintext with our private key, generating our ciphertext. Next, we hide the ciphertext inside of a media file, such as an image.
When our recipient receives the file, she'll first extract the ciphertext and then use the public key to decrypt the ciphertext.
By combining these two methods, we increase the security of a message. Anyone intercepting the message would need to know that there's an encrypted file inside the image file before attempting to crack the encryption.
And that's it for this lesson. In this video, we discussed the different ways of combining cryptographic methods. We looked at how hybrid cryptographic models combine the efficiency of symmetric methods and the convenience of asymmetric methods and how EFS takes advantage of this combination. Then we discussed digital signatures and how they can be used to provide message authentication and non-repudiation. Finally, we went over combining encryption with steganography and how this combination can be used to hide ciphertext inside of a media file.

3.2.2 Hardware-Based Encryption Devices (Lesson Video)

Transcript:

Many encryption systems are managed by the operating system or other software, but there are also some hardware options for encryption. In this lesson, we'll look at the two of the most common hardware options, the TPM and HSM.

The Trusted Platform Module, or TPM, is a physical chip that resides on the motherboard. It's responsible for providing some cryptographic services. Using a hardware chip means that the encryption system itself can't be attacked by malicious software. The latest version, TPM 2.0, was released in 2014. TPM chips can be used for checking key system components at startup and for protecting and generating encryption keys and passwords.
One key function of the TPM chip is to check key system components during startup. When the system is turned on, the TPM checks to make sure everything seems normal. If the TPM detects anything out of sorts, it doesn't allow the system to boot, which prevents data from being extracted.
The TPM is also used to store and generate encryption keys. In essence, TPM provides an encrypted lockbox where user passwords, encryption keys, and digital certificates can be kept safe.
For example, Windows 10 can pull these keys directly from the TPM without loading them into the RAM, where they would be more vulnerable to attack.
When encryption keys are generated, they usually need a random number to be generated too. This is a weak spot in encryption since most software number generators contain patterns and are not truly random.
The TPM chip can be used to generate completely random numbers for the encryption process, which increases the effectiveness of the encryption keys.
A TPM chip can also greatly increase the security of a system. Some popular Windows features such as BitLocker and Credential Guard rely on the TPM chip to perform at their most secure level.
A hardware security module, or HSM, is very similar to a TPM. You might also hear these devices referred to as a Personal Computer Security Module or Secure Application Module. One of key differences is that an HSM is a removable device, whereas the TPM is built into the motherboard.
One major benefit of HSMs is that they're more powerful than TPM chips. HSMs are designed to be powerful cryptographic devices with better hardware capabilities. This allows HSMs to perform multiple security operations for multiple users. Some HSM devices can even be attached to a server to handle cryptographic functions for an entire network.

HSM devices perform many of the same functions as a TPM, such as generating and storing encryption keys, but they can also be used to generate and validate digital signatures and generate keys used in smart cards. Consumer-grade HSM devices have become much more affordable over the past few years, making them more accessible than before.
And that's it for this lesson. In this video, we've covered two options for hardware-based encryption. The TPM chip is built into the motherboard. It checks key hardware components during startup and generates and stores encryption keys. And HSMs are add-on devices that perform many of the same functions as a TPM chip, but are much more powerful.

3.2.3 Verify Device for TPM (Demo Video)

Transcript:

TPM, or Trusted Platform Module is a security device used to secure hardware. One of the most common ways is using BitLocker with a TPM. When combined, BitLocker encryption and a TPM provide more security than standard software encryption alone. To determine if your device has a TPM, you can access the BIOS. Look for an option related to Trusted Computing. Within this section, you'll find an option to enable or disable TPM. Some BIOS settings might not explicitly mention TPM, so Trusted Computing could be the option you're seeking if you don't see TPM mentioned. This concept should apply to most BIOS settings; you'll just need to locate the menu based on your motherboard model.

With newer versions of Windows, such as Windows 11, TPM 2.0 is required. Most computers manufactured within the last 5 years should have this capability. If your computer is older, there's a chance it may have an older TPM module or no TPM at all. In Windows, there are several ways to verify TPM. You can navigate to the Device Manager and go to Security Devices, where you'll find a listing for TPM. If Windows cannot detect a TPM, you'll see nothing in this section. You can also check the status of this device to ensure it's functioning correctly. The key thing to look for is to ensure there are no question marks or errors associated with this device. If there are, it may indicate a device or driver issue that needs attention.
Another method to check your TPM is by examining your security processor in Windows Security. Access Windows Security by typing security in the search bar, then navigate to Device Security and click on Security Processor Details. If your TPM is functioning properly, you will see related details here. In case you encounter issues with your TPM, you have the option to troubleshoot and clear TPM information. Note that you should only clear TPM if you intend to remove previously configured TPM data. There could be situations where a computer was previously used with BitLocker, and clearing the TPM may become necessary.
Since we're discussing BitLocker, let's explore some settings related to it. If you navigate to BitLocker from the Start menu, you will notice that encryption is not currently enabled. One area not accessible via a Windows search bar is TPM management. If you are familiar with older versions of Windows, this window should look familiar. It offers similar options to the troubleshooting area in security, such as clearing your TPM or preparing it for use. Since the status is set to Ready to Use, you should be able to enable BitLocker and utilize TPM for enhanced security.
That concludes this demonstration. In this demo, we have shown you various methods for verifying the presence of a TPM and ensuring it is ready for use with BitLocker encryption.

3.2.4 Cryptographic Implementation Facts

This lesson covers the following topics:

- Hybrid models
- Obfuscation
- Encryption with steganography
- Key management
- Secure enclaves
- Cryptoprocessors

Hybrid Models

Operating systems, applications, and other components of information systems typically use a hybrid cryptography system. A hybrid cryptography system combines the strengths of hashing, symmetric encryption, and asymmetric encryption, depending on the needs of the project or service. An example of these strengths are:

- Use symmetric encryption for fast and efficient encryption of bulk data.
- Use hashing to verify message integrity.
- Use asymmetric encryption for authentication and non-repudiation.
- Use asymmetric encryption for secure exchange of symmetric encryption keys (for example, by encrypting the key used for symmetric encryption prior to sharing the key with the recipient). Using asymmetric cryptography for encryption is best for small pieces of data.

A hybrid cryptosystem combines the efficiency of symmetric methods and the convenience of asymmetric methods. One example of this is Microsoft's Encrypting File System, or EFS. Microsoft's EFS uses the following steps to encrypt data:

1. A file is encrypted using a File Encryption Key (FEK).
2. The FEK is encrypted with the user's public asymmetric key.
3. The file is sent to the intended recipient.
4. The user's private key is used to decrypt the FEK.
5. The FEK is used to decrypt the file.

One of the biggest weaknesses of the EFS is that the user's private key is essentially their user password. If the password is weak, the encryption will also be weak.

Obfuscation

Obfuscation is the art of making a message or data difficult to find. It is security by obscurity, which is normally deprecated. There are some uses for obfuscation technologies, however:

- Steganography (literally meaning "hidden writing") embeds information within an unexpected source, a message hidden in a picture, for instance. The container document or file is called the *covertext* . The message can be encrypted by some mechanism before embedding it, providing confidentiality. The technology can also provide integrity or non-repudiation; for example, it could show that something was printed on a particular device at a particular time, which could demonstrate that it was genuine or fake, depending on the context.
- Data masking can mean that all or part of the contents of a database field are redacted by substituting all character strings with "x," for example. A field might be partially redacted to preserve metadata for analysis purposes. For example, in a telephone number, the dialing prefix might be retained, but the subscriber number is redacted. Data masking can also use techniques to preserve the original format of the field.
- Tokenization means that all or part of the value of a database field is replaced with a randomly generated token. The token is stored with the original value on a token server or token vault, separate from the production database. An authorized query or app can retrieve the original value from the vault if necessary, so tokenization is reversible. Tokenization is used as a substitute for encryption because, from a regulatory perspective, an encrypted field has the same value as the original data.

Data masking and tokenization are used for de-identification. De-identification obfuscates personal data from databases so that it can be shared without compromising privacy.

Encryption with Steganography

There has been an increased amount of research done on how to best combine encryption with steganography. The process essentially follows the steps below:

1. Encrypt plaintext with a private key to generate ciphertext.

2. The ciphertext is hidden inside a media file, such as an image, using steganography.
3. The recipient extracts the ciphertext and decrypts it using the matching public key.
4. Because the ciphertext is hidden in the image file, someone intercepting the message would have to know it is there before being able to decrypt it.

Key Management

Key management refers to operational considerations for the various stages in a key's lifecycle. A key's lifecycle may involve the following stages:

- **Key Generation** — creates an asymmetric key pair or symmetric secret key of the required strength using the chosen cipher.
- **Storage** — prevents unauthorized access to a private or secret key and protects against loss or damage.
- **Revocation** — prevents use of the key if it is compromised. If a key is revoked, any data that was encrypted using it should be re-encrypted using a new key.
- **Expiration and Renewal** — gives the certificate a "shelf-life," increasing security. Every certificate expires after a certain period. Certificates can be renewed with the same key pair or with a new key pair.

A decentralized key management model means that keys are generated and managed directly on the computer or user account that will use the certificate. This does not require any special setup, so it is easy to deploy. However, it makes the detection of key compromises more difficult.

Some organizations prefer to centralize key generation and storage using a tool such as a key management system . In one type of cryptographic key management system, a dedicated server or appliance is used to generate and store keys. When a device or app needs to perform a cryptographic operation, it uses the Key Management Interoperability Protocol (KMIP) to communicate with the server.

Secure Enclaves

A key pair or secret key can be generated and stored in the file system on a desktop or server computer running a general-purpose OS. This has a number of drawbacks, however:

- **A cryptographic key needs to be generated using a random process** . A key generation system with a high degree of disorder—or entropy—ensures that any value from the possible keyspace has the same chance of being selected as any other. Unfortunately, computer hardware and software are extremely low entropy—computers process instructions in an entirely deterministic way. A computer can use pseudo RNG (PRNG) software that is still deterministic but able to approximate a high level of disorder. Better security is obtained by true random number generator (TRNG) hardware. This uses a source of entropy, such as noise or air movement, as a nondeterministic seed for generating the key value.
- **A key stored in the file system is only as secure as any other file.** It could easily be compromised via the user credential or physical theft of the device. It is also difficult to ensure that key access is fully audited. Ideally, cryptographic storage is tamper-evident. This means that it is known immediately when a private or secret key has been compromised, and it can be revoked and any ciphertexts re-encrypted with a new key.

```
GnuPG needs to construct a user ID to identify your key.

Pseudo RNG working during key generation using GPG. This method gains entropy from user mouse and keyboard usage.

These drawbacks can be addressed using a cryptoprocessor for key generation and storage.

Cryptoprocessors

A cryptoprocessor performs operations such as decryption and signing on behalf of apps. This means that the key material never leaves the cryptoprocessor. Because it is dedicated to a single function, the cryptoprocessor hardware has a smaller attack surface than a general-purpose computer.

Hardware security module appliance in a rack-mounted form factor. (Images © 123RF.com.)

There are two main ways of implementing cryptoprocessor hardware:

Cryptoprocessor Hardware	Description

Trusted Platform Module (TPM)	A TPM is a cryptoprocessor implemented as a module within the CPU on a computer or mobile device. TPMs are produced to different version specifications, with versions 1.2 and 2.0 in current use. Version 2.0 is not backward compatible with version 1.2. Beginning with Windows 10 version 1607, Microsoft required that TPM 2.0 be enabled by default on all new computers.
	• A TPM is required to check the integrity of startup files and components in BitLocker implementations.
	  ○ The TPM generates a hash of the startup files to verify the integrity of those files.
	  ○ Additionally, the TPM creates a hash of system components. This hash acts as a validation check of the system to ensure that system components have not changed. The hash can also be used to uniquely identify the system.
	• Windows Credential Guard requires the computer to have a TPM chip installed.
	  ○ A TPM provides protection for virtual-based security encryption keys that are stored in the firmware. This helps protect against attacks involving a physically present user with BIOS access.
	• A TPM can generate truly random numbers, thus preventing entropy.
	• TPM provides full support for asymmetric encryption; therefore, it can generate public and private keys.
	• A TPM also provides encrypted storage for user passwords, encryption keys, and digital certificates.
	• Windows 10 can pull stored keys directly from the TPM without loading them into the RAM, where they would be more vulnerable to an attack.

Hardware security module (HSM)	An HSM is cryptoprocessor hardware implemented in a removable or dedicated form factor, including rack-mounted appliances, plug-in PCIe adapter cards, and USB-connected security keys. It is also possible to provision an HSM as a virtual appliance.

Cryptoprocessor Hardware	Description
	HSMs provide cryptographic functions such as: • Generate and store encryption keys. • Generate and validate digital signatures. • Generate keys used in smart cards. HSMs traditionally come in the form of a plug-in card or an external security device that can be attached directly to the computer system. These devices offer some benefits over TPM chips. • HSMs are more powerful and can perform more powerful cryptographic functions quicker. • HSMs can perform multiple cryptographic functions simultaneously. • HSMs can be attached to a network and handle cryptographic functions for multiple users across the network. Hardware Security Modules are also known as: • Personal Computer Security Module (PCSM) • Secure Application Module (SAM) • Hardware cryptographic devices • Cryptographic modules

Vendors can certify their products against the Federal Information Processing Standard 140 Level 2 (FIPS 140-2) to establish trust in the market.

Using a cryptoprocessor means that keys are not directly accessible via the file system. The cryptoprocessor interacts with applications that need to access the key via an application programming interface (API) that implements PKCS#11.

One vulnerability in this system is that decrypted data needs to be loaded into the computer's system memory (RAM) for applications to access it. This raises the potential for a malicious process to gain access to the data via some type of exploit. This vulnerability can be mitigated by implementing a secure enclave . A trusted execution environment (TEE) secure enclave, such as Intel Software Guard Extensions, can protect data stored in system memory so that an untrusted process cannot read it. A secure enclave is designed so that even processes with root or system privileges cannot access it without authorization. The enclave is locked to a list of one or more digitally signed processes.

3.2.5 Practice Questions (Section Quiz)

q_comb_cryp_encrypt_secp8

Which form of cryptography is BEST suited for bulk encryption because it is so fast?

Answers:

- Hashing cryptography
- Public key cryptography

- ***Symmetric key cryptography**
- Asymmetric cryptography

Explanation:

Symmetric cryptography is best suited for bulk encryption because it is much faster than asymmetric cryptography.

Hashing is not used for encryption; it is only used to verify the integrity of data.

Public key cryptography, also known as asymmetric cryptography, is best suited for small amounts of data. Often, asymmetric cryptography is used to exchange symmetric cryptography keys, and then the symmetric cryptography keys are used to encrypt communication traffic.

q_comb_cryp_expiration_date_secp8

You are a cybersecurity manager at a financial institution. Your team is responsible for managing the cryptographic keys used for secure transactions.

Recently, there has been an increase in attempted cyber attacks on your institution.

Which of the following key management strategies would be MOST effective in maintaining the security of your cryptographic keys under these circumstances?

Answers:

- You decide to generate new keys for each transaction, but keep the old keys stored in the system for future reference.
- You decide to revoke all current keys and generate new ones, informing all users to update their keys immediately.
- ***You decide to set an expiration date for all current keys and inform users that they will need to renew their keys after this date.**
- You decide to centralize key generation and storage, moving all keys to a single server for easier management.

Explanation:

Setting an expiration date for all current keys and requiring users to renew their keys after this date is the correct and proactive approach to key management in this scenario. This ensures that keys are regularly updated, reducing the chance that an attacker can use an old key to gain unauthorized access. It also provides a structured and predictable process for users, which can help prevent confusion or errors.

While generating new keys for each transaction can enhance security, keeping old keys stored in the system can pose a risk. If an attacker gains access to these old keys, they might be able to decrypt past transactions and gain access to sensitive information.

Revoking all current keys and generating new ones can be a drastic measure that may cause unnecessary disruption. It can also confuse users and lead to potential errors or security risks if not managed properly.

While centralizing key generation and storage can simplify management, it can also create a single point of failure. If the server where the keys are stored is compromised, all keys could be at risk. It's generally better to distribute keys across multiple secure locations.

q_comb_cryp_hsm_secp8

A cyber technician reduces a computer's attack surface by installing a cryptoprocessor that a plug-in PCIe adaptor card can remove.

What type of cryptoprocessor can support this requirement?

Answers:

- ***HSM**
- CRL
- PKI
- TPM

Explanation:

A hardware security module (HSM) meets the analyst's needs in this scenario. An HSM is a cryptoproccessor that implements hardware through a removable or dedicated form factor, such as plug-in peripheral component interconnect express (PCIe) adaptor cards.

Not viable in this scenario, a certificate revocation list (CRL) provides a summation of all revoked and suspended certificates and must be accessible to anyone relying on the validity of the certificate authority's certificates.

Public key infrastructure (PKI) is the framework that establishes trust in using public key cryptography to sign and encrypt messages via digital signatures.

A trusted platform module (TPM) is a cryptoprocessor implemented as a module within the CPU on a computer or mobile device.

q_comb_cryp_obfuscation_secp8

You are a cybersecurity analyst at a large corporation. Your team has been tasked with securing sensitive data within the company's database. One of the strategies you are considering is obfuscation.

Which of the following scenarios would be the most appropriate application of obfuscation?

Answers:

- You use obfuscation to hide the company's financial data within an image file on the company's public website.
- You use obfuscation to hide the source code of the company's proprietary software within a text document.
- ***You use obfuscation to hide employee personal data within a database field by substituting character strings with x.**
- You use obfuscation to hide the company's network architecture within a PDF document.

Explanation:

You use obfuscation to hide employee personal data within a database field by substituting character strings with *x* is correct. This is a form of obfuscation known as data masking, which is often used to protect sensitive data, such as personal information. By replacing actual data with placeholder characters, you can prevent unauthorized access to the data while maintaining the original data structure for authorized use.

You use obfuscation to hide the company's financial data within an image file on the company's public website.
is incorrect. While this is a form of obfuscation (specifically steganography), it is not a good practice to hide sensitive data like

financial information on a public website. Even though it's hidden within an image file, if someone knows what to look for, they could potentially extract and exploit this information.

Obfuscating source code can make it more difficult for unauthorized users to understand and misuse it, but it's not a foolproof method of protection. If the obfuscated code is reverse-engineered, the original code could be exposed. Additionally, obfuscation does not prevent someone from copying the obfuscated code and using it elsewhere.

While obfuscation could be used to hide details about the company's network architecture, it's not the best method for protecting this type of information. A more effective approach would be to implement robust network security measures, such as firewalls, intrusion detection systems, and regular network monitoring.

q_comb_cryp_secure_enclaves_01_secp8

You are a cybersecurity architect at a tech company that is developing a new mobile payment application. The application will handle sensitive user data including credit card information and personal identification numbers (PINs).

Which of the following strategies would best leverage the concept of secure enclaves to protect this sensitive data?

Answers:

- You decide to store all sensitive data in a secure enclave within the application, accessible only through a secure API.
- You decide to store all sensitive data in a secure enclave on the company's main server, accessible only by senior IT staff.
- ***You decide to store all sensitive data in a secure enclave on each user's device, accessible only with the user's unique PIN.**
- You decide to store all sensitive data in a secure enclave within the application, accessible to all application users.

Explanation:

Storing sensitive data in a secure enclave on each user's device and making it accessible only with the user's unique PIN is the best strategy. This approach leverages the concept of secure enclaves by isolating sensitive data on a per-user basis, and it adds an additional layer of security by requiring the user's unique PIN for access.

While storing sensitive data in a secure enclave within the application and making it accessible only through a secure API is a good practice, it does not fully leverage the concept of secure enclaves. The data is still potentially vulnerable if the application itself is compromised.

Storing all sensitive data in a secure enclave on the company's main server could create a single point of failure. If the server is compromised, all data could be at risk. Additionally, this does not leverage the concept of secure enclaves as a method of isolating sensitive data on a per-user basis.

Storing sensitive data in a secure enclave within the application and making it accessible to all application users does not provide adequate protection for the data. This approach does not leverage the concept of secure enclaves, which are designed to isolate sensitive data and limit access to it.

q_comb_cryp_secure_enclaves_02_secp8

As a cybersecurity expert, you are tasked with implementing a secure enclave in your company's new mobile banking application.

Which of the following statements best describes the primary function and benefit of a secure enclave in this context?

Answers:

- A secure enclave is a protected area within the application's code that prevents users from making unauthorized transactions.
- ***A secure enclave is a separate, isolated environment within the device's processor where sensitive data can be securely stored and processed.**
- A secure enclave is a network security tool that monitors and controls incoming and outgoing network traffic based on predetermined security rules.
- A secure enclave is a cloud-based storage system where encrypted data is stored and can only be accessed with the correct decryption key.

Explanation:

A secure enclave is a separate, isolated environment within the device's processor. It is designed to securely store and process sensitive data, even in the event that the rest of the device is compromised.

While a secure enclave does provide a level of protection, it is not located within the application's code and it does not directly prevent users from making unauthorized transactions. Its primary function is to securely store and process sensitive data.

Monitoring and controlling incoming and outgoing network traffic refers to a firewall, not a secure enclave. A firewall is a network security device that monitors and controls network traffic, while a secure enclave is a hardware-based security feature of a processor.

While a secure enclave does involve the storage of sensitive data, it is not a cloud-based storage system. A secure enclave is a hardware-based feature that exists within a device's processor.

q_comb_cryp_stenography_secp8

Combining encryption with steganography involves several steps.

From the list on the left, drag a description of a step or result in this process to the correct order on the right.

Answers:

- The ciphertext is hidden inside of a media file, such as an image, using steganography.
- Anyone intercepting the message would have to know its there before being able to decrypt it.
- Encrypt plaintext with a private key to generate ciphertext.
- The recipient extracts the ciphertext and decrypts it using the matching public key.

Explanation:

There has been an increased amount of research done on how to best combine encryption with steganography. The process essentially follows the steps below:

1. Encrypt plaintext with a private key to generate ciphertext.
2. The ciphertext is hidden inside of a media file, such as an image, using steganography.
3. The recipient extracts the ciphertext and decrypts it using the matching public key.
4. Because the ciphertext is hidden in the image file, someone intercepting the message would have to know its there before being able to decrypt it.

q_comb_cryp_tpm_01_secp8

What is the main function of a TPM hardware chip?

Answers:

- ***Generate and store cryptographic keys**
- Perform bulk encryption in a hardware processor
- Control access to removable media
- Provide authentication credentials on a hardware device

Explanation:

A Trusted Platform Module (TPM) is a hardware cryptoprocessor that resides on the motherboard. This hardware is used to store and generate cryptographic keys. These keys are used for encryption and authentication, but the TPM does not perform the actual encryption.

A smart card is a hardware device containing a digital certificate. The smart card can be used for authentication.

Special hardware processors perform bulk encryption in hardware rather than software. These processors typically encrypt data using AES or encrypt network traffic using IPsec.

q_comb_cryp_tpm_02_secp8

Which of the following functions are performed by a TPM?

Answers:

- ***Create a hash of system components**
- Perform bulk encryption
- Encrypt network data using IPsec
- Provide authentication credentials

Explanation:

A Trusted Platform Module (TPM) is a hardware cryptoprocessor that resides on the motherboard. This hardware is used to store and generate cryptographic keys. The TPM also generates hash values of system components. The hash value verifies that startup components have not been modified. Because each system has a unique hash value, the hash can also be used as a form of identification for the system.

Keys generated by the TPM are used for encryption and authentication, but the TPM does not perform the actual encryption.

A smart card is a hardware device containing a digital certificate. The smart card can be used for authentication.

Special hardware processors perform bulk encryption in hardware rather than software. These processors typically encrypt data using AES or encrypt network traffic using IPsec.

q_comb_cryp_tpm_03_secp8

A cyber security analyst wants to reduce the attack surface for a computer that contains top secret data. The analyst installs a cryptoprocessor as a module within the central processing unit (CPU) on the designated computer to accomplish this.

What type of cryptoprocessor is the analyst installing?

Answers:

- ***TPM**
- HSM
- CRLs
- PKI

Explanation:

A trusted platform module (TPM) meets the analyst's needs in this scenario. A TPM is a cryptoprocessor implemented as a module within the CPU on a computer or mobile device.

Not viable in this scenario, a hardware security module (HSM) is a cryptoprocessor that implements hardware through a removable or dedicated form factor, such as plug-in peripheral component interconnect express (PCIe) adaptor cards.

A certificate revocation list (CRL) provides a summation of all revoked and suspended certificates and must be accessible to anyone relying on the validity of the certificate authority's certificates.

Public key infrastructure (PKI) is the framework that establishes trust in using public key cryptography to sign and encrypt messages via digital signatures.

3.3 Hashing

As you study this section, answer the following questions:

- What is the output of hashing called?
- What are the five characteristics of a hash function?
- What are some common uses for hashing?
- What type of attack takes advantage of hash collisions?
- What are the main hashing algorithms used?

In this section, you will learn to:

- Use hashes.
- Compare MD5 hashes.

The key terms for this section include:

Term	Definition
Hashing algorithm	A function that converts an arbitrary-length string input to a fixed-length string output. A cryptographic hash function does this in a way that reduces the chance of collisions, where two different inputs produce the same output.
Cryptographic primitive	A single hash function, symmetric cipher, or asymmetric cipher.
Digital signature	A message digest encrypted using the sender's private key that is appended to a message to authenticate the sender and prove message integrity.

Salt	A security countermeasure that mitigates the impact of precomputed hash table attacks by adding a random value to ("salting") each plaintext input.
Key stretching	A technique that strengthens potentially weak input for cryptographic key generation, such as passwords or passphrases created by people, against brute force attacks.
Secure Hash Algorithm (SHA)	A cryptographic hashing algorithm created to address possible weaknesses in multi-domain authentication (MDA). The current version is SHA-2.
Message-Digest Algorithm 5 (MD5)	A cryptographic hash function producing a 128-bit output.

This section helps you prepare for the following certification exam objectives:

Exam	Objective
CompTIA Security+ SY0-701	1.4 Explain the importance of using appropriate cryptographic solutions. • Encryption ○ Algorithms • Hashing • Salting • Digital signatures
TestOut Security Pro	4.0 Data Security 4.2 Implement Encryption Technologies 4.2.1 Encrypt data communications 4.2.2 Encrypt files

3.3.1 Hashing (Lesson Video)

Transcript:

When you're transferring or downloading files, it's important to know that the file is legitimate and hasn't been altered in any way. This is what hashes are for. In this lesson, we'll discuss how hashing works, some common ways they're used, what hashing collisions are, and how to reduce collisions.

Hashing is the process of generating a fixed-length hexadecimal string value from any file type or data.
Let's look at an example. We have an image file that we can run through a hashing algorithm and get a hexadecimal output. This output is the hash. All hashing functions are one-way functions. This means that the hash cannot be reversed. In other words, you can't decipher a hash and find out what the original data was.
A proper hash function has five characteristics. First, it should be deterministic, meaning the same data will always generate the same hash. Next, the hash generation needs to be quick and efficient, and it can't be reverse-engineered.

The hash function should also be collision-resistant and exhibit the avalanche effect, meaning that that if even one tiny bit in the data is changed, the new hash will be completely different.
For example, using the MD5 algorithm, the hash for the message 'Hello world" would look like this. If we capitalize the W and generate a new hash using the same algorithm, we get a very different hash.
There are a few reasons why you may want to generate a hash for some of your data,
such as verifying file integrity, providing digital signatures, and verifying passwords. Let's look at each in more detail.
We download files from the internet all the time. When you do this, you're not always sure that a file is safe and hasn't been tampered with. By providing a hash of the original file, you can verify that the file you downloaded is legitimate.
For example, when an application developer finalizes their program, they can generate a hash of the app and the upload the app to their website along with the generated hash.
Later, this company's website gets hacked, and the hacker replaces the program file with another malicious program by the same name.
When a customer downloads the file, they can generate a hash and compare it to the original hash. Because the app file has been replaced, the hashes won't match, and they'll know that the file has been changed and they shouldn't run it.
Hashing is also used when creating a digital signature for an important message. Using a hash of the data along with our private encryption key, a digital signature is created. This is the equivalent of signing our name to a physical document. When the recipient receives the message, they can verify the digital signature to ensure that the data or message is legitimate.
Hashing is also used to protect passwords. Instead of sending the password in clear text, only a hash of the password is sent. For example, when you use a Microsoft account to sign in to a Windows system, your password is first encrypted using a special hashing algorithm called NTLM. That hash is then checked by Windows, and if it matches, you're signed in.
One of the problems with using hashed passwords is that several online sites have collected massive databases containing a hash for tens of million of possible passwords. Once a hash has been captured, it can be compared with the hashes found in the database, quickly resulting in the password used to create the hash. To keep this from happening, most hashes now also incorporate what's known as a salt.
Salting the hash means that a random number of characters are added to the password before the hash is created.
For example, if the password to be hashed was this, a salt such as this may be added. The string to be hashed becomes this. Since the salt is randomly generated each time, even if the same password is used, and can be varying lengths, it's virtually impossible to create a database containing all the possible salted passwords.
Using hashing helps meet the goals of Information Security by providing file integrity, non-repudiation, confidentiality, and authentication.
Hashing is a very good file verification method, but it's not 100% foolproof. Depending on the algorithm used, there's a potential for hash collisions. A hash collision occurs when two completely different files generate the same hash. A rainbow table attack takes advantage of this weakness. Let's go through the process.
A rainbow table is a table of passwords and their generated hashes. A hacker can use this table to match a captured hash with one in the table. When a match is found, the hacker knows the password, or in the case of a collision, they'll at least know a password that will work.
For example, let's say a user's sign-in password is TestOut, which generates this hash. In the hacker's rainbow table, the password of SecurityPro has also generated the same hash value. This is a hash collision. Taking advantage of this collision, the hacker can gain access to the system using the password of SecurityPro, since it will send the same hash value that the real password uses.
You can reduce the risk of a hash collision by using an algorithm that will generate a longer hash and by salting the hash.
That's it for this lesson. We've discussed how hashing works, including the characteristics of a proper hash function. We reviewed some of the ways hashing is used, including verifying file integrity, digital signatures, and passwords. We ended by discussing hash collisions and how hackers can exploit them using rainbow tables.

3.3.2 Hashing Algorithms (Lesson Video)

Transcript:

Hashing is the process of generating a fixed-length hexadecimal string value from any file type or data. That output is often referred to as the hash or message digest. Hashing can be used to verify file integrity, create digital signatures, provide password verification, and more.

There are different hashing algorithms or functions for different uses. The most common algorithms are MD5 and SHA, and two alternative hash functions are HMAC and RIPEMD. In this lesson, we'll look at these algorithms and discuss how they work.

Message-Digest Algorithm version 5, commonly called MD5, was developed by Ron Rivest in 1991. This hash function generates a 128-bit message digest, but it can't be used for security purposes any longer. One of the key features of a proper hash function is that it's resistant to hash collisions, but the MD5 algorithm is extremely susceptible to collisions. Today, MD5 is mainly used to verify file integrity.

The Secure Hash Algorithm, or SHA, is a family of hashes that are government-standard algorithms and were published by NIST starting in 1993. SHA-2 was published in 2001 and has become one of the standard hash functions in use today. We see it implemented frequently in security communications protocols such as TLS and SSL, PGP, SSH, and IPSec. This algorithm can generate message digests that are 224, 256, 384, or 512 bits in size.

SHA-3 was released in 2015, but it's not meant to replace SHA-2, as it's still a secure hashing method. Because SHA-2 is so heavily integrated in our standard online transactions and communications, it doesn't make sense to switch over yet. SHA-3 uses a completely different process than SHA-2, but the message digests are compatible with SHA-2. What this means for us is that when SHA-2 is inevitably compromised, SHA-3 will be available to take over immediately.

Hash-Based Message Authentication Code, or HMAC, is a type of message authentication code. Like a digital signature, HMAC allows a user to verify that a file or message is legitimate.

When using HMAC, the message sender provides a secret key that's used with a hash function, such as MD5 or SHA, to create a message authentication code. The recipient then uses the key to verify both the integrity and authenticity of the message.

In 1992, a new hash function called RIPE Message Digest, or RIPEMD, was developed based on the MD4 algorithm. In 1996, due to security issues discovered in RIPEMD, a group of Belgian researchers published four updated algorithms. While it's not as popular as SHA-2, the 160-bit function is used frequently with Bitcoin and other cryptocurrencies.

That's it for this lesson. In this lesson, we discussed MD5 and SHA, the most popular hashing functions. MD5 is mostly used for file verification, while SHA-2 is widely used in many security communications protocols. We also discussed two alternative hashing functions, HMAC and RIPEMD. HMAC is used for message or file verification, and RIPEMD is mostly used with Bitcoin and other cryptocurrencies.

3.3.3 Hashing Facts

This lesson covers the following topics:

- Hashing
- Salting and key stretching
- Hashing uses
- Hash collisions
- Hashing algorithms
- Comparing hash values

Hashing

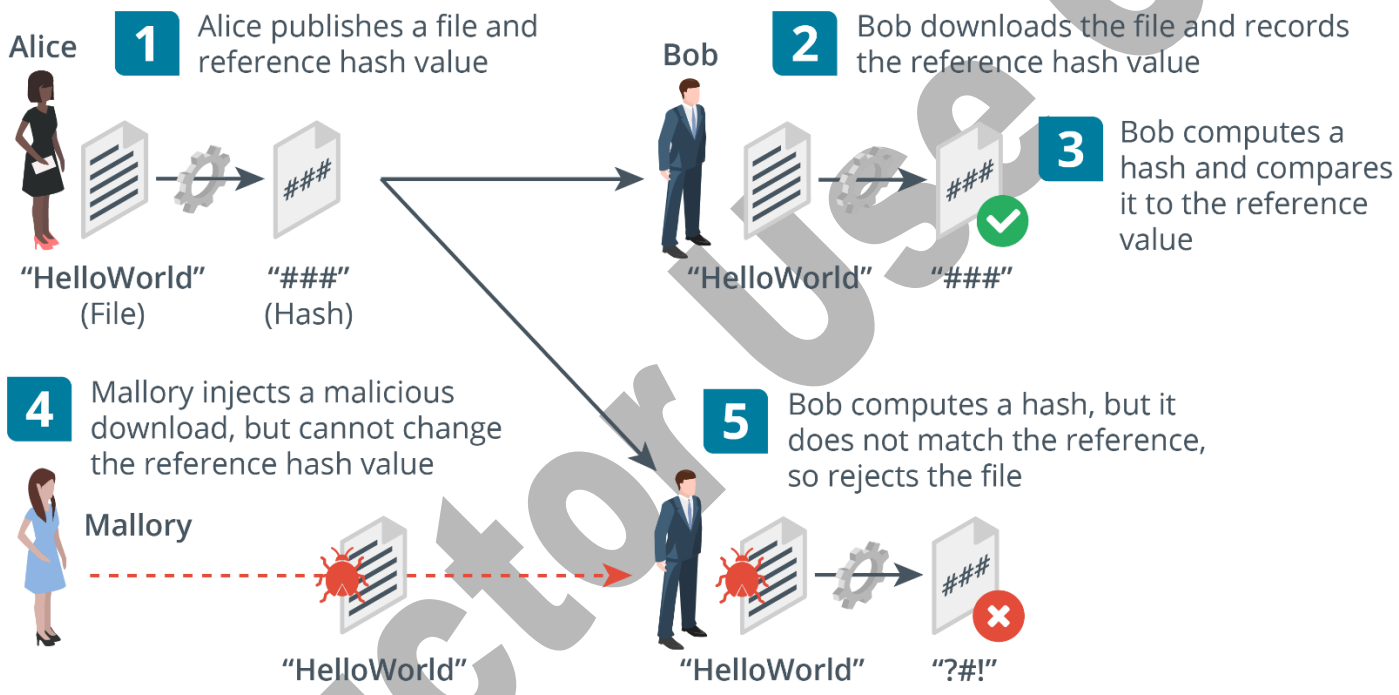
A cryptographic hashing algorithm produces a fixed-length string of bits from an input plaintext that can be of any length. The output can be referred to as a hash or message digest. The function is designed so that it is impossible to recover the plaintext data from the digest (one-way) and that different inputs are unlikely to produce the same output (a collision).

A hashing algorithm is used to prove integrity. For example, Bob and Alice can compare the values used for a password in the following way:

- Bob has a digest calculated from Alice's plaintext password. Bob cannot recover the plaintext password value from the hash.
- When Alice needs to authenticate to Bob, they type their password, convert it to a hash, and send the digest to Bob.
- Bob compares Alice's digest to the hash value on file. If they match, Bob can be sure that Alice typed the same password.

As well as comparing password values, a hash of a file can be used to verify the integrity of that file after transfer.

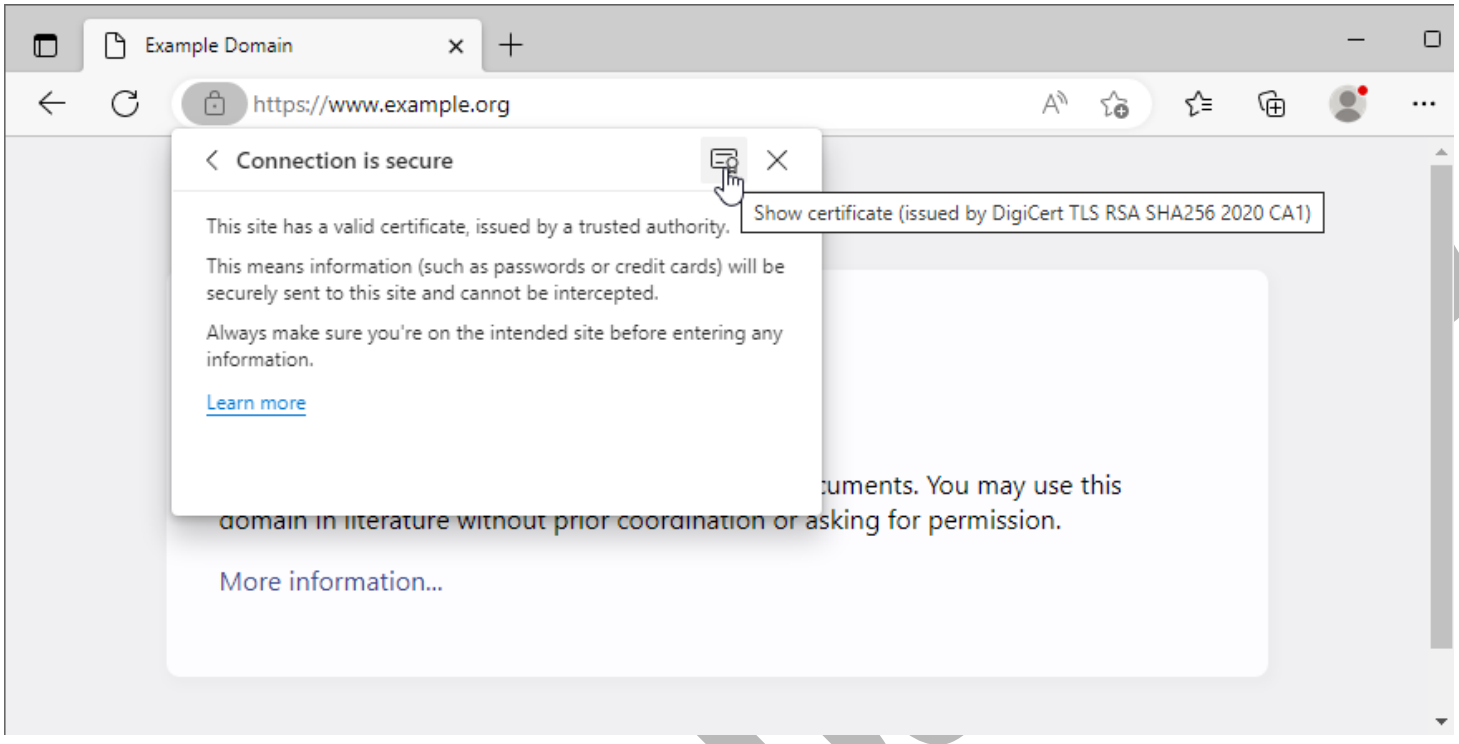
- Alice runs a hash function on the setup.exe file for their product. They publish the digest on their website with a download link for the file.
- Bob downloads the setup.exe file and makes a copy of the digest.
- Bob runs the same hash function on the downloaded setup.exe file and compares it to the reference value published by Alice. If it matches the value published on the website, Bob assumes the file has integrity.
- Consider that Mallory might be able to substitute the download file for a malicious file. Mallory cannot change the reference hash, however.
- This time, Bob computes a hash that does not match, leading him to suspect that the file has been tampered with.



Confirming a file download using cryptographic hashes (Images © 123RF.com)

A single hash function, symmetric cipher, or asymmetric cipher is called a cryptographic primitive . A complete cryptographic system or product is likely to use multiple cryptographic primitives within a cipher suite. The properties of different symmetric/asymmetric/hash types and specific ciphers for each type impose limitations on their use in different contexts and for different purposes.

Encryption can be used to ensure confidentiality. Cryptographic ciphers can also be used for integrity and authentication. If you can encode a message in a way that no one else can replicate, then the recipient of the message knows with whom they are communicating (that is, the sender is authenticated).

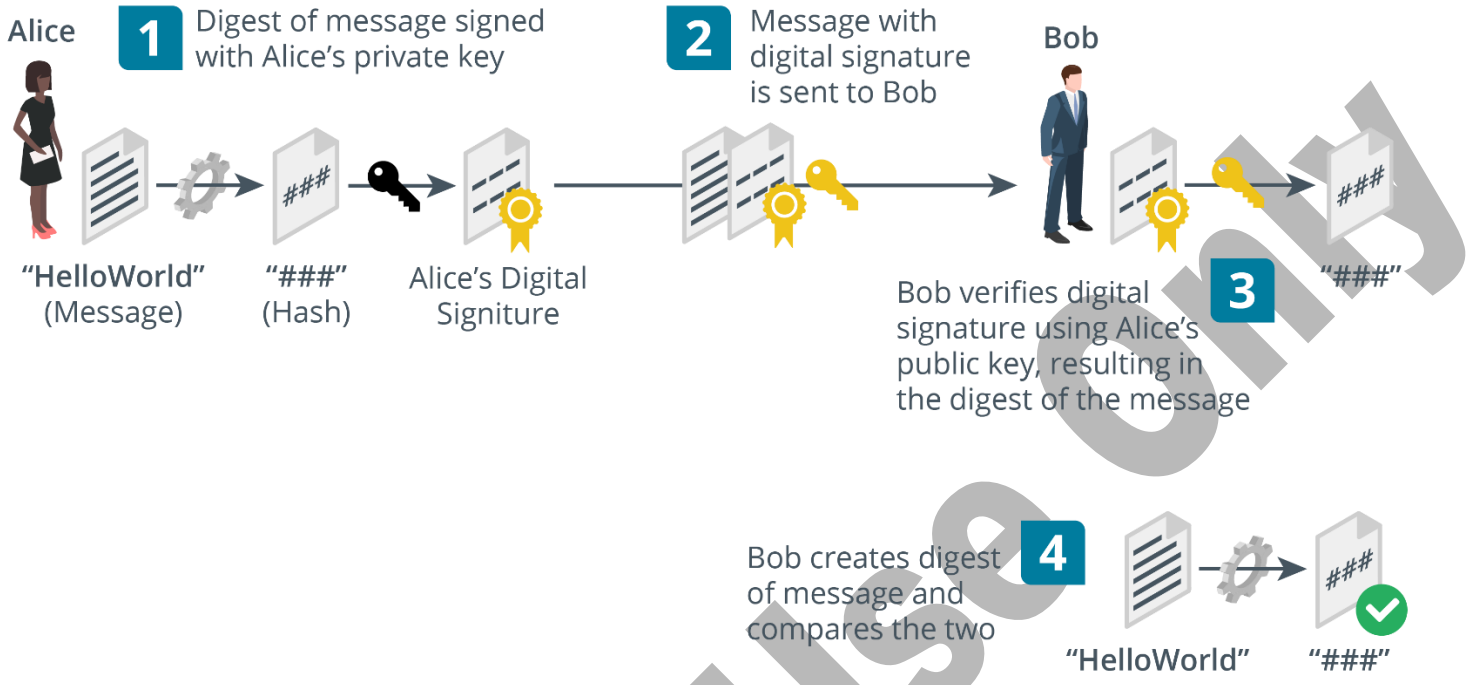


Cryptography allows subjects to identify and authenticate themselves. The subject could be a person or a computer, such as a web server.

Public key cryptography can authenticate a sender because they control a private key that produces messages in a way that no one else can. Hashing proves integrity by computing a unique fixed-size message digest from any variable length input. These two cryptographic ciphers can be combined to make a digital signature :

- The sender (Alice) creates a digest of a message using a pre-agreed hash algorithm, such as SHA256, and then performs a signing operation on the digest using her chosen asymmetric cipher and private key.
- Alice attaches the digital signature to the message and sends both the signature and the message to Bob.
- Bob verifies the signature using Alice's public key, obtaining the original hash.
- Bob then calculates his own digest for the document (using the same algorithm as Alice) and compares it with Alice's hash.

If the two digests are the same, then the data has not been tampered with during transmission, and Alice's identity is guaranteed. If the data had changed or a malicious user (Mallory) had intercepted the message and used a different private key to sign it, the hashes would not match.



Message authentication and integrity using digital signatures (Images © 123RF.com).

There are several standards for creating digital signatures. The Public Key Cryptography Standard #1 (PKCS#1) defines the use of RSA's algorithm. The Digital Signature Algorithm (DSA) uses a cipher called ElGamal, but the Elliptic Curve DSA (ECDSA) is now more widely used. DSA and ECDSA were developed as part of the US government's Federal Information Processing Standards (FIPS).

Salting and Key Stretching

The values used for a private or secret key must be selected at random. If there is something predictable about the way the value of the key was derived, it has less entropy. Low entropy is a particular concern whenever a cryptographic system makes use of user-generated data, such as a password. Users tend to select low entropy passwords because they are easier to remember. This type of data is too short and ordered to be a good "seed" for key generation. Salting and key stretching help to protect password-derived cryptographic secrets from discovery through cryptanalysis.

Salting

Cryptographic hash functions are often used for password storage and transmission. A hash cannot be decrypted back to the plaintext password that generated it. Hash functions are one way. However, passwords stored as hashes are vulnerable to brute force and dictionary attacks.

A threat actor can generate hashes to find a match for a hash captured from network traffic or a password file. A brute force attack simply runs through every possible combination of letters, numbers, and symbols. A dictionary attack creates hashes of common words and phrases.

Both these attacks can be slowed down by adding a salt value when creating the hash. A salted hash is computed as follows:

(salt + password) * SHA = hash

A unique, random salt value should be generated for each user account. This mitigates the risk that if users choose identical plaintext passwords, there would be identical hash values in the password file. The salt is not kept secret because any system verifying the hash must know the value of the salt. It simply means that an attacker cannot use precomputed tables of hashes. The hash values must be recompiled with the specific salt value for each password.

Key Stretching

Key stretching takes a key generated from a user password plus a random salt value and repeatedly converts it to a longer and more disordered key. The initial key may be put through thousands of rounds of hashing. This might not be difficult for the attacker to replicate, so it does not actually make the key stronger. It does slow the attack down because the attacker has to do extra processing for each possible key value. Key stretching can be performed using a particular software library to hash and save passwords when created. The Password-Based Key Derivation Function 2 (PBKDF2) is widely used for this purpose, notably as part of Wi-Fi Protected Access (WPA).

Hashing Uses

Hashing is often used for the following:

Hash Use	Description
File integrity	Hashes are often used to prove the integrity of downloaded files. When a file is uploaded to a site, a hash can be generated. When the recipient downloads the file, they can create a hash of that file. If the recipient's hash matches the hash of the original file, you know that: • The downloaded file is complete (no missing parts). • The downloaded file was not corrupted during the transfer. • The downloaded file is the same as the original and has not been altered by inserting malicious code or replaced with a virus or malware file. For this reason, files available for download are typically not encrypted, as the hash proves their data integrity.
Digital signatures	A digital signature is a combination of asymmetric encryption and hashing values. A signature provides confidentiality, integrity validation, strong authentication, and non-repudiation. Typically, a digital signature works as follows: 1. A hash value is generated for a message. 2. The hash value is asymmetrically encrypted using the sender's private key. Non-repudiation is provided because only the sender could have encrypted the hash using the private key (only the sender knows the private key). 3. The encrypted hash value and the message are sent. 4. The recipient decrypts the hash using the sender's public key. 5. The recipient hashes the message. 6. Message integrity and sender authenticity (non-repudiation) are confirmed if the two hash values match.
Secure logon credential exchange	Hashes can be used to secure logon credentials during an exchange. The password is used as the key to perform a hash on a text value, and only the hashed value is passed (not the password). The receiving host uses the same method to compare the hashes to verify the identity of the user. Examples of protocols that use this method are: • Challenge-Handshake Authentication Protocol (CHAP)

Hash Use	Description
	• New Technology LAN Manager (NTLM) • Kerberos Passwords can be further secured by salting the hash. This is the process of adding random characters at the beginning or end of the password to generate a completely different hash. If a hacker intercepts the hash, they must also know which portion is the salt before beginning to crack the hash.

Hash Collisions

Hashing is a good file verification method, but it is not perfect. Depending on the algorithm used, there is a potential for hash collisions. A hash collision occurs when two completely different files generate the same hash. Rainbow table attacks take advantage of hash collisions.

- A rainbow table is a table of passwords and their generated hashes. A hacker can use this table to try to match hashes instead of the actual password.
- Hash collisions can be reduced using an algorithm that generates a longer hash and by salting the hash. Salt is random data used as an additional input to the function that hashes data.

Hashing Algorithms

The two most popular implementations of hash algorithms are the Secure Hash Algorithm (SHA) and Message-Digest Algorithm #5 (MD5). Depending on the use, there are different hashing algorithms which can be used. The following table covers some of the more common algorithms.

Hashing Algorithm	Description
Secure Hash Algorithm (SHA)	SHA is a family of hashes. • SHA is a government standard and is considered the strongest algorithm. • First published in 1991 by the National Institute of Standards and Technology (NIST). • SHA-2 was published in 2001 and has become one of the standard hash functions used today. • Used in many security protocols such as TLS, SSL, PGP, SSH, and IPSec. • Generates message digests that are 224, 256, 384, or 512 bits in size. • The longer digests are considered more secure, with the most popular variant being SHA256, which produces a 256-bit digest. SHA-3 was published in 2015 but is not meant to replace SHA-2. SHA-2 has yet to be cracked. NIST wanted an alternative available for people to use. Message digests generated by SHA-3 are fully compatible with SHA-2.

Hashing Algorithm	Description
	 Computing an SHA value from a file (Screenshot used with permission from Microsoft.)
Message-Digest Algorithm 5 (MD5)	MD5 was developed by Ron Rivest in 1991. • MD5 generates a 128-bit message digest. • Many security vulnerabilities have been discovered with MD5. As such, it is no longer viable for security purposes. • MD5 is extremely susceptible to hash collisions. • MD5 is mainly used for file integrity. • MD5 is not considered safe for use, but it might be required for compatibility between security products.
Hash-Based Message Authentication Code (HMAC)	HMAC is a type of message authentication code. Like a digital signature, HMAC allows a user to verify that a file or message is legitimate. • The message sender provides a secret key that is used with a hash function, such as MD5 or SHA, to create a message authentication code. • The recipient then uses the key to verify both the integrity and authenticity of the message.
RACE Integrity Primitives Evaluation Message Digest (RIPEMD)	RIPEMD (RACE Integrity Primitives Evaluation Message Digest, or RIPE Message Digest) is a family of cryptographic hash functions that was first developed in 1992 as part of the EU's RIPE project. The first version was based on the MD4 function. In 1996, in response to security issues discovered in the first version, Belgian researchers developed four updated algorithms. • RIPEMD-128 • RIPEMD-160 • RIPEMD-256 • RIPEMD-320 RIPEMD is not as popular as SHA-2 but is used frequently with Bitcoin and other cryptocurrencies.

Comparing Hash Values

Being able to compare the hash of a file after it has been downloaded to a known good hash helps verify that the file was not altered in transit.

To compare file hashes, you must first generate a hash for the file after it has been downloaded. This can be done using the PowerShell cmdlet named **Get-FileHash** . In the following example, a hash is being generated for the file named Download.zip. The **-a** (or – algorithm) switch specifies the algorithm to use when generating the hash. It is followed by the desired algorithm, in this case, MD5.

Example: **Get-FileHash Download.zip -a md5**

Algorithm	Hash	Path
MD5	A9ESDS4B7288811EC080948E10909A	C: \Downloads\Download.zip

Sample output from Get-FileHash.

Companies often provide a separate file containing the hash of a file that can be downloaded and used to compare to the hash you generate for the downloaded file. This is often in the form of a text file. To view the hash, you can simply open the text file or use PowerShell's **Get-Content** cmdlet to extract the hash from the file.

Example: **Get-Content Download.txt**
Sample Output: **4A84C7958C246E39439C784349F4ZDB4**

Once you have access to the two hashes, you can visually compare them to see if they are the same, or an easier way is to use the **-eq** command to compare to two hash values.

Example: **"39C784349F4ZDB44A84C7958C246E394" -eq "4A84C7958C246E39439C784349F4ZDB4"**

The output will be "True" if the hashes match or "False" if they do not match.

3.3.4 Using Hashes (Demo Video)

Transcript:

In this demonstration, we'll explore how hashing works. I've already downloaded a hashing utility that does both MD5 and SHA-1 hashes. It's called Microsoft File Checksum Integrity Verifier. I've placed it at the root of C: in a folder named FCIV.

As you can see, I have the fciv.exe file, the README.txt that tells you about the file and how to use it, and a little TestOut.txt file that I've created. The name of the executable is obviously fciv.exe, and it uses an MD5 hashing algorithm by default, but it can also use SHA-1.
Let's practice creating a hash of a file. I have this Testout.txt file, and I've entered some text into it. It just says "TestOut." Let's go ahead and close the file.
The first thing we need to do is go to the command prompt. This hashing tool runs off the command prompt. We need to do is get to the correct folder, FCIV at the root of C. Now we're in the right folder, and we can check the directory. You can see the files in the directory, the executable, and the ReadMe. If we open the ReadMe file, it'll show you some of the information about using this file. It shows you some features, and it shows you the syntax for using these features.
Let's go back. We're not going to do anything complicated today. We're going to keep it simple and just create some hashes.
First, we're going to do an MD5 hash. By default, this tool will hash an MD5, and you don't have to state MD5. (You can, but you don't have to.) Let's go ahead and hash our text file. Let's type in â€˜fciv.exe'. Then all we have to do is type â€˜testout.txt'. You can see it's just created our hash for us. The resulting hash is displayed, and MD5 is a 128-bit hashing algorithm, so the output is composed of 128 zeroes and ones. To make it easier to read, the output is then converted from binary to hexadecimal notation. Each hexadecimal character is four bits long, so the hash is composed of 32 hexadecimal characters.

Let's try to modify our Testout.txt file. Suppose that someone has intercepted this file in transit and modified it. Let's just add a period here, at the end. We'll save it and close the file. This isn't much of a change.
Let's say maybe the attacker tried to modify the file without being too obvious. We'll run the hash again. Just press the up arrow and press Enter. We can see that we get a completely different hash value. It's not even close to the original one--it's completely different. If you're using hashing as part of your cryptographic solution, you'll know if data has been modified. The hashes will be marked completely differently.
Let's go back to the file and change it back to the way it was. If we run the hash again, notice the hash is now back to its original value. The fact that it was modified in the past doesn't affect the hash value. The hashing algorithm only evaluates the current content of the data. In this case, the current content is identical to what we had originally hashed, so the hash value is the same. Identical data going into the same hashing algorithm will produce the exact same output.
Let's go ahead and rename the Testout file from Testout to Testout1. We're going to just add a 1 here, and that's it. We have to change this a little bit, just add a 1. Notice that the hash is identical again. The hashing algorithm doesn't care what label you put on the data. It only evaluates the data.
Let's look at an example of SHA, or secure hashing algorithm. Specifically, we're going to use SHA-1. This is similar to MD5. In this tool, we'll use a similar syntax, but we actually have to specify SHA-1.
Let's go back, and we're going to change our file back to TestOut. Instead of entering the fciv.exe, we actually have to specify our SHA-1, because, by default, it does MD5. We have to specify that we want to use SHA-1. Let's go ahead and type in â€˜fciv.exe sha-1 testout.txt'.
All right, so now we can see our file, our SHA-1 hash. Similarly, if we go in and edit our Testout text and add the period, just like we did with MD5, and we save and close, run the same hash again, you can see, we got a different hash, just like with MD5. If we change it back, get rid of the period at the end, save, and run the command again, the same thing occurs as with MD5: we'll get the original hash back.
That's it for this demonstration. This demo provided an overview of how hashing works. We reviewed hashing with MD5 and SHA-1.

3.3.5 Compare an MD5 Hash (Simulation)

Scenario

You are the IT administrator at a small corporate office. You just downloaded a new release for a program you use. You need to ensure the file was not altered before receiving it. Another file containing the original file hash was also downloaded. Both files are located in the C:\Downloads folder.

In this lab, your task is to use MD5 hash files to confirm that the Release.zip file was unaltered.

- Generate a file hash for the Release.zip file.
- View the hash of the original file stored in the **release821hash.txt** file.
- Using the applicable command, compare the original hash of the Release.zip file to its calculated hash to see if they match.

> You can highlight text in PowerShell and right-click it to copy the text to the active line. If using Chromebooks, highlight the desired hash amount and then click on the touchpad using two fingers to copy and paste the value.

- Answer the question.

Explanation

Complete this lab as follows:

1. View the files in the C:\Downloads folder.
    a. Right-click **Start** and select **Windows PowerShell (Admin)** .

b. At the prompt, type **cd C:\downloads** and press **Enter** to navigate to the directory that contains the files.
c. Type **dir** and press **Enter** to view the available files.

2. Confirm that the Release.zip file is unaltered.
   a. Type **get-filehash Release.zip -a md5** and press **Enter** to view the MD5 hash.
   b. Type **get-content release821hash.txt** and press **Enter** to view the known hash contained in the .txt file.
   c. Type ***"new hash"* -eq *"known hash"*** and press **Enter** to determine whether the file hashes match.

   - The new hash is the hash generated by the **get-filehash *file_name* -a md5** command.
   - The known hash is the hash generated by the **get-content *file_name.txt*** command.
   - Include the quotation marks and the file extensions with the file names in the commands.

3. Answer the question.
   a. From the top right, select **Answer Questions** .
   b. Answer the question.
   c. Select **Score Lab** .

3.3.6 Practice Questions (Section Quiz)

q_cryp_hash_collision_secp8

When two different messages produce the same hash value, what has occurred?

Answers:

- Birthday attack
- ***Collision**
- Hash value
- High amplification

Explanation:

A collision occurs when two different messages produce the same hash value.

A birthday attack is a brute force attack in which the attacker hashes messages until one with the same hash is found.

A hash value is the result of a compressed and transformed message (or some type of data) into a fixed-length value.

High amplification means a small change in the message results in a big change in the hashed value.

q_cryp_hash_digest_secp8

Hashing algorithms are used to perform which of the following activities?

Answers:

- Encrypting bulk data for communications exchange.
- ***Creating a message digest.**
- Providing a means for exchanging small amounts of data securely over a public network.

- Providing for non-repudiation.

Explanation:

Hashing algorithms are used to create a message digest to ensure that data integrity is maintained. A sender creates a message digest by performing the hash function on the data files that are transmitted. The receiver performs the same action on the data received and compares the two message digests. If they are the same, the data was not altered.

Symmetric algorithms are used to encrypt bulk data for communications exchange.

Asymmetric algorithms provide a means for exchanging small amounts of data securely over a public network.

Both symmetric and asymmetric algorithms provide non-repudiation.

q_cryp_hash_get-filehash_secp8

You are a system administrator at a software company. You have been tasked with verifying the integrity of a large software update file that has been downloaded from the internet. The software provider has provided a SHA256 hash of the file for verification purposes.

You decide to use the **Get-FileHash** command in PowerShell to calculate the hash of the downloaded file.

Which of the following scenarios best demonstrates the correct use of the **Get-FileHash** command for this purpose?

Answers:

- ***You use the Get-FileHash command to calculate the hash of the downloaded file and compare it with the hash provided by the software provider. If the hashes match, you assume the file has not been tampered with.**
- You use the Get-FileHash command to calculate the hash of the downloaded file and send it to the software provider for verification.
- You use the Get-FileHash command to calculate the hash of the downloaded file and compare it with the hash of the original file on your system. If the hashes match, you assume the file has not been tampered with.
- You use the Get-FileHash command to calculate the hash of the downloaded file and compare it with the hash of another file downloaded from the internet. If the hashes match, you assume the file has not been tampered with.

Explanation:

The proper use of the **Get-FileHash** command is for verifying the integrity of a file. By calculating the hash of the downloaded file and comparing it with the hash provided by the software provider, you can verify that the file has not been tampered with during download.

The software provider has already provided a hash for verification purposes. You should not need to send your calculated hash back to them for verification.

Comparing the hash of the downloaded file with the hash of the original file on your system will not verify the integrity of the downloaded file. The original file on your system may not be the same version as the downloaded file, so their hashes may not match even if the downloaded file has not been tampered with.

Comparing the hash of the downloaded file with the hash of another file downloaded from the internet will not verify the integrity of the downloaded file. The two files are likely to be different, so their hashes should not match.

q_cryp_hash_hash_01_secp8

Which of the following is used to verify that a downloaded file has not been altered?

Answers:

- ***Hash**
- Symmetric encryption
- Asymmetric encryption
- Private key

Explanation:

A hash is a function that takes a variable-length string (message) and compresses and transforms it into a fixed-length value. Hashes ensure the data integrity of files and messages in transit. For example, when users post files for download, they often create a hash value for the file. After you download the file, you can create a hash using the same algorithm. If the hash values match, you know that the file you have matches the original file.

Symmetric encryption is typically used for fast data encryption.

Asymmetric encryption is used for encrypting small amounts of data or exchanging keys used with symmetric encryption.

A private key is one of the keys used in asymmetric encryption.

q_cryp_hash_hash_02_secp8

You have just downloaded a file. You create a hash of the file and compare it to the hash posted on the website. The two hashes match.

What do you know about the file?

Answers:

- ***Your copy is the same as the copy posted on the website.**
- You can prove the source of the file.
- No one has read the file contents as it was downloaded.
- You are the only one able to open the downloaded file.

Explanation:

A hash is a function that takes a variable-length string (message) and compresses and transforms it into a fixed-length value. Hashes ensure the data integrity of files and messages in transit. The sender and the receiver use the same hashing algorithm on the original data. If the hashes match, it is assumed that the data is unmodified.

Hashes do not ensure confidentiality (in other words, hashes are not used to encrypt data).

Non-repudiation proves the source of a file and is accomplished using digital signatures.

q_cryp_hash_hash_04_secp8

A cybersecurity analyst working for a financial institution handles sensitive customer data and must ensure its integrity and confidentiality. Part of the analyst's responsibilities is to evaluate the hashing algorithms used to protect the data's integrity.

Which statement accurately describes the purpose and functionality of hashing algorithms in data security?

Answers:

- ***Hashing algorithms generate a fixed-size output (a hash value), which represents the input data and is unique to each input.**
- Hashing algorithms encrypt data to make it unreadable to unauthorized users.
- Hashing algorithms use a public and private key pair to transmit data over the network securely.
- Hashing algorithms compress data to reduce storage requirements and improve performance.

Explanation:

Hashing algorithms generate a fixed-size output called a hash value, which represents the input data and is unique to each input. Additionally, they generate unique, fixed-size output (hash value) for any given input. The hash value is a digital fingerprint of the input data and is unique to each input, ensuring data integrity and allowing for efficient data comparison.

Hashing algorithms do not relate to encryption but rather to data integrity verification.

Hashing algorithms do not involve the use of public and private key pairs.

Hashing algorithms do not relate to data compression; instead, they create a unique representation of the input data.

q_cryp_hash_hmac_secp8

Which of the following is a message authentication code that allows a user to verify that a file or message is legitimate?

Answers:

- SHA
- MD5
- RIPEMD
- ***HMAC**

Explanation:

Hash-based Message Authentication Code (HMAC) is a type of message authentication code. Like a digital signature, HMAC allows a user to verify that a file or message is legitimate.

SHA is a family of hashes that is used in many different security protocols.

MD5 was developed in 1991 and is no longer viable for security purposes.

RIPEMD is a family of cryptographic hash functions that was first developed in 1992 as part of the EU's RIPE project.

q_cryp_hash_rainbow_secp8

An attacker is attempting to crack a system's password by matching the password hash to a hash in a large table of hashes he or she has.

Which type of attack is the attacker using?

Answers:

- Cracking
- Brute force
- ***Rainbow**
- RIPEMD

Explanation:

A rainbow attack uses rainbow tables. A rainbow table is a table of passwords and their generated hashes. A hacker can use this table to try to match hashes instead of the actual password.

Cracking is the process of finding a password.

A brute force attack does not use a table of hashes.

RIPEMD is a family of cryptographic hash functions that was first developed in 1992 as part of the EU's RIPE project.

q_cryp_hash_ripemd_secp8

What is the primary use of the RACE Integrity Primitives Evaluation Message Digest (RIPEMD)?

Answers:

- It is primarily used for file compression.
- ***It is primarily used in Bitcoin and other cryptocurrencies.**
- It is primarily used for creating digital watermarks.
- It is primarily used for email encryption.

Explanation:

RIPEMD, specifically the RIPEMD-160 variant, is used in the creation of Bitcoin wallet addresses. It is part of the process that converts a user's public key into a Bitcoin address.

RIPEMD is a cryptographic hash function, not a compression algorithm. It is used to ensure data integrity and authenticity, not to reduce the size of data files.

While cryptographic hash functions can be used in the creation of digital watermarks, this is not the primary use of RIPEMD. Digital watermarking typically involves embedding information into a digital signal, which is not the function of RIPEMD.

While cryptographic hash functions are used in various aspects of email encryption, RIPEMD is not specifically designed or primarily used for this purpose. Other protocols and algorithms, such as RSA and AES, are more commonly used for email encryption.

q_cryp_hash_salting_secp8

What is the process of adding random characters at the beginning or end of a password to generate a completely different hash called?

Answers:

- ***Salting**
- Deterministic
- Collision

- Avalanche

Explanation:

Salting is the process of adding random characters at the beginning or end of the password to generate a completely different hash. If a hacker intercepts the hash, he or she would need to also know which portion is the salt before beginning to crack the hash.

Deterministic is a characteristic of a hash function that means the same data always generates the same hash.

A collision is when two different pieces of data generate the same hash.

The avalanche effect states that changing any bit of data results in a completely different hash.

q_cryp_hash_secure_logon_secp8

You are a security analyst at a large corporation. The corporation is implementing a new system that requires secure logon credential exchange between different departments.

The corporation decides to use a cryptographic hashing algorithm for this purpose.

Which of the following scenarios best demonstrates the correct use of hashing for secure logon credential exchange?

Answers:

- ***Each department calculates a hash of their password and sends it to the other departments. The receiving department compares this hash with the hash of the sending department's password they have on file. If the hashes match, the receiving department assumes the sending department has authenticated itself.**
- Each department sends their password to the other departments. The receiving department calculates a hash of the received password and compares it with the hash of the sending department's password they have on file. If the hashes match, the receiving department assumes the sending department has authenticated itself.
- Each department calculates a hash of their password and sends the actual password along with the hash to the other departments. The receiving department then verifies the password by comparing it with the hash.
- Each department shares their passwords with each other, calculates the hash of their own password, and if the hashes match, they assume they have authenticated each other.

Explanation:

The proper use of a hashing algorithm for secure logon credential exchange includes each department calculating a hash of their password and sending it to the other departments. The receiving department compares this hash with the hash of the sending department's password they have on file. If the hashes match, the receiving department can be sure that the sending department has authenticated itself.

Departments should never send their actual passwords, even if the receiving department is using hashing for authentication. The purpose of using hashing is to avoid sending the actual password.

Departments should never send their actual passwords, even if they are also sending the hash. The purpose of using hashing is to avoid sending the actual password.

Departments should never share their actual passwords with each other, even if they are using hashing for authentication.

q_cryp_hash_weak_secp8

Which of the following is no longer valid for security purposes?

Answers:

- ***MD5**
- SHA-1
- DES
- AES

Explanation:

MD5 is the weakest hashing algorithm. It produces a message digest of 128 bits. Many security vulnerabilities have been discovered with MD5. As such, it is no longer viable for security purposes.

SHA-1 is more secure because it produces a 160-bit message digest.

Both DES and AES are symmetric encryption algorithms. DES is weaker than AES.

q_md5_hash

Do the file hashes match?

Answers:

- No
- No
- Yes
-

3.4 Encryption

As you study this section, answer the following questions:

- Which editions of Windows include Encrypting File System (EFS)?
- Why would you create a Data Recovery Agent (DRA)?
- Which standard does Pretty Good Privacy (PGP) and GNU Privacy Guard (GPG) follow?
- What partition/volumes are created when implementing BitLocker?
- What are three methods of database encryption?

In this section, you will learn to:

- Encrypt files using EFS.
- Encrypt files using GPG.
- Configure BitLocker with a Trusted Platform Module (TPM).

The key terms for this section include:

Term	Definition
Data at rest	Information that is primarily stored on specific media, rather than moving from one medium to another.
Data in transit (or data in motion)	Information that is being transmitted between two hosts, such as over a private network or the internet.
Data in use (or data in processing)	Information that is present in the volatile memory of a host, such as system memory or cache.
Transport/communication encryption	Encryption scheme applied to data-in-motion, such as WPA, IPsec, or TLS.
Key exchange	Any method by which cryptographic keys are transferred among users, thus enabling the use of a cryptographic algorithm.
Hash-based Message Authentication Code (HMAC)	A method used to verify both the integrity and authenticity of a message by combining a cryptographic hash of the message with a secret key.
Full disk encryption (FDE)	Encryption of all data on a disk (including system files, temporary files, and the page file) that can be accomplished via a supported OS, third party software, or at the controller level by the disk device itself.
Self-encrypting drives (SED)	A disk drive where the controller can automatically encrypt data that is written to it.
Key Encryption Key (KEK)	In storage encryption, the private key that is used to encrypt the symmetric bulk media encryption key (MEK). This means that a user must authenticate to decrypt the MEK and access the media.
Opal Storage Specification	Standards for implementing device encryption on storage devices.

This section helps you prepare for the following certification exam objectives:

Exam	Objective

CompTIA Security+ SY0-701	1.4 Explain the importance of using appropriate cryptographic solutions.
	• Encryption
	  ○ Full-disk
	  ○ Database

	• Tools ○ Trusted Platform Module (TPM) 2.5 Explain the purpose of mitigation techniques used to secure the enterprise. • Encryption
TestOut Security Pro	4.0 Data Security 4.2 Implement Encryption Technologies 4.2.1 Encrypt data communications 4.2.2 Encrypt files

3.4.1 Encrypting File System (Lesson Video)

Transcript:

Microsoft's Encrypting File System, or EFS, was introduced with NTFS version 3 and has been included in every version of Windows since Windows 2000, except for in the Home editions.

EFS makes it simple for users to encrypt files on their Windows systems.
In this lesson, we'll look at the EFS encryption process, recovering data, and some security considerations with EFS.
EFS combines the speed of symmetric encryption with the convenience of asymmetric encryption.
However, keep in mind that EFS is used to encrypt individual files or folders on the system, not the entire drive. You would have to use BitLocker for that.
When you want to encrypt a file, Windows generates a pseudo-random number called the File Encryption Key, or FEK.
Windows uses the FEK with the AES encryption algorithm to encrypt the file.
To further protect everything, the FEK is then encrypted using the user's public key and stores the encrypted FEK in the file's header in a special location called the Data Decryption Field, or DDF.
The decryption process is just the opposite.
The user's private key is used to first unlock the DDF and get the FEK. The FEK is then used to decrypt the file.
By combining the security of the symmetric keys and the convenience of the asymmetric keys, Microsoft has made it easy for users to encrypt their data.
By default, the only user that can decrypt files is the user who encrypted them. If that user account becomes corrupted somehow or the password is forgotten, any encrypted files are lost. To prevent this, we need to setup a Data Recovery Agent, or DRA.
The Data Recovery Agent, or DRA, is simply another account that can decrypt data that's been encrypted by other users on a Windows operating system.
In older versions of Windows, the system administrator was automatically configured as the DRA, but in newer versions, the DRA is not automatically defined.
Instead, you have to go into Group Policy on the local computer to setup the DRA.
When working on a Domain network, the DRA is defined in Active Directory.
Keeping the decryption keys safe is vital to protecting your data and being able to access it when needed.
To do this, you can backup the decryption keys to a USB drive. Then, if something catastrophic happens to the Windows system, you still have access to the files, you'll be able to decrypt the files using the backup of the decryption keys.
When using EFS, there are some security issues you need to keep in mind, such as what happens when files are moved.
If you move or copy an encrypted file to a different location on the same partition, or to another NTFS partition, your file will stay encrypted.
However, if you move or copy a file to a FAT based partition, the file will be decrypted automatically, as these file systems don't support encryption.

We need to be careful with this because by default, USB drives are formatted with the FAT32 or exFAT file systems as these are most compatible with other operating systems.
When you copy an encrypted file over, you won't be notified that the file is decrypted. This can lead to some serious security issues.
The other security concern is that the user's private key is protected only by their password. If the user has a weak password and the system is compromised, all encrypted files are vulnerable. It's absolutely vital that users have strong passwords and follow proper password security protocols.
That's it for this lesson.
In this lesson we discussed EFS and how the encryption process works.
We then looked at why a Data Recovery Agent should be created so there's a second account that can access encrypted files in case something happens.
And finally, we reviewed some security considerations with EFS including moving encrypted files and using strong passwords.

3.4.2 Encrypt Files (Demo Video)

Transcript:

In this demonstration, we're going to talk about protecting sensitive files with encryption using the Encrypting File System, or EFS, on Windows. We'll demonstrate with files that are stored on an NTFS file system volume. Let's get started.

We begin by going down here to File Explorer. I'm going to go to my C: drive, and you can see that I've created this folder called Confidential. I have two different files in here.
The first one is my Org Chart, and the second one is where I keep my performance reviews. Now, the Org Chart file isn't really sensitive at all. Pretty much everybody in the organization knows who reports to who.
The Performance Reviews file, on the other hand, is highly confidential. I don't want any of my employees to access it. One thing I can do to prevent this is to encrypt the file so that only my user account can open it.
To do this, I right-click the file, go to Properties, and then to Advanced. I can either compress the file's contents or encrypt it. Notice that you can't select both at the same time. We're just going to select Encrypt contents to secure data, click OK, and click Apply.
We're prompted to either encrypt the file and its parent folder, which would encrypt the entire Confidential folder and everything in it, or the file alone. In this case, we want to select Encrypt only the file. Select OK and then Ok again. You can see that, right here, there's a little lock on the icon now. That means that the file is now fully encrypted.
To clarify, I'm logged in as the TestOut user right now. At this point, only this account is allowed to access this file's contents. If I double-click it, I can easily open it up and see everything. I read that all my employees have met expectations. That means I have some really great employees.
Let's move on to testing what we've done by logging on as a different user—Kim Sanders—whose user account is named ksanders.
Now, ksanders is a member of my administrative group, and so she's obviously an administrator on this system. Let's go ahead and go back to the file system the same way we did before—File Explorer > C: drive > Confidential.
We see the encrypted Performance Reviews file here. Let's try to open it. You can see that access to this file has been denied to this user because, although she's a system administrator, she doesn't have access to this specific file.
This file wasn't set up with NTFS permissions that are blocking the access. It's the encryption. Since ksanders is an administrator, she technically has access to all the data that other users have on the system. Let's go ahead and close this window.
By default, only the user who encrypted the file is allowed to decrypt it and access its contents, but we can change that.
We're going to go ahead and sign out of ksanders and log back in to our TestOut user account again.
We'll navigate again to File Explorer > C: drive > Confidential > Performance Reviews. Right-click, go to Properties, and click the Advanced button. Here you can see that the Details option is now available, whereas before we encrypted the file, it wasn't.
If we go into Details, we can specify other users that we want to give file access to. Let's click Add. Notice that ksanders isn't listed here. It just shows my TestOut user.
The issue is that my TestOut user has a certificate. It was created automatically when I encrypted this file. The ksanders user, however, doesn't have a certificate.

That means that before we can add the ksanders user account to the list of users who are allowed to access the Performance Reviews file, we have to create a certificate for her, which we do in the ksanders profile. So let's go back out again and switch our user. Sign out. Now log back in as ksanders and provide the password.
With the Start button, search for Control Panel > User Accounts > User Accounts again. Here, we'll go to Manage your file encryption certificates. This wizard easily walks us through creating a file encryption certificate. We just need to hit Next. Then we click Create a new certificate and Next again.
We have some options here. The basic one is to create a self-signed certificate. If you had a smart card or if your domain had a certificate authority, you could use either of those as well. Click Next. We're prompted to back up the certificate after it's created. That's a really good idea. Let's say that something were to happen and we needed to re-create the ksanders user account. The new key won't be the same, and ksanders will lose access to all the files that she encrypted on the system.
But if you have a backup of the original encryption key, that'll be the one that's used to encrypt the file. Instead of creating a new key, you just restore your old one from backup. You won't lose access to anything.
We won't worry about that specifically today, but just know that this is important to think about. I'll just click Back up later and Next to move on. We need to check the I'll update my encrypted files later box and click Next as well before we can keep going.
You now see that our certificate is created. Click Close. Now what we need to do is go back in to our TestOut user account and allow Kim Sanders access via that certificate.
Let's close this and go back to Sign out. Now we're going to log back in as our TestOut user once again. Let's go back to our file system and to the Confidential folder.
We'll return to the Performance Reviews file, click Properties, go to Advanced, and then to Details. We need to click Add, select More choices, and then you can see the ksanders certificate here. Just select it and click OK.
We're warned here that the certificate is self-signed, and it's not issued by a trusted root certificate authority. It wants to know if we trust it. Since we created it, we should obviously trust it. I click OK, OK again, and Apply.
And now, one last time, we're going to sign out and back in to the ksanders user account. Select Kim Sanders and back through File Explorer > C: drive > Confidential > Performance Reviews and double-click. As you can see, the file opened without a problem.
Now ksanders has access to an encrypted file that was encrypted by another user.
So that's it for this demonstration. In this demo, we talked about EFS file encryption on Windows. We first talked about how this works with the NTFS file system. Then we encrypted a sensitive file for the TestOut user account. After that, we switched users and created a certificate for the ksanders user account, and we assigned that account access to the encrypted file with the security certificate.

3.4.3 Encrypt Files with EFS (Simulation)

Scenario

You share a computer with other users at work. You want to secure the contents of the Finances folder so that unauthorized users cannot view its contents.

In this lab, your task is to:

- Encrypt the **D:\Finances** folder and all of its contents.
- Give John file access to the encrypted **D:\Finances\2023report.xls** file by adding the encryption certificate.

Explanation

Complete this lab as follows:

1. Open the D:\ drive.
    a. From the Windows taskbar, select **File Explorer** .
    b. From the left pane, select **This PC** .
    c. From the right pane, double-click **Data (D:)** .
2. Encrypt the Finances folder.

a. Right-click **Finances** and then select **Properties** .
b. Select **Advanced** .
c. Select **Encrypt contents to secure data** and then select **OK** .
d. Select **OK** to close the properties dialog.
e. Select **OK** to confirm the attribute changes.

3. Give John authorization to modify the encrypted 2023report.xls file.
   a. Double-click **Finances** .
   b. Right-click **2023report.xls** and then select **Properties** .
   c. Select **Advanced** .
   d. Select **Details** .
   e. Select **Add** .
   f. Select **John** and then select **OK** .
   g. Select **OK** as many times as needed to close all remaining dialogs.

3.4.4 PGP and GPG (Lesson Video)

Transcript:

When you're encrypting files or emails, you need the help of a utility. Windows automates this process with either BitLocker or EFS. In a Unix-based operating system, such as Linux or Apple's OS X, we can use GNU Privacy Guard, or GPG. GPG is based on an older utility, Pretty Good Privacy, or PGP. In this lesson, we'll cover how both utilities work and how to use them.

PGP is an encryption program first developed in 1991 based on the OpenPGP standard. PGP combines the use of symmetric and asymmetric keys and can be used to send encrypted messages and encrypt data.
To encrypt data, PGP generates a large, random one-time use session key that's used for encryption. The session key is then encrypted using the receiver's public key, and both are combined to send the encrypted message.
When the receiver gets the message, they use their private key to decrypt the session key, which is then used to decrypt the message.
Even though PGP is an old utility, it's still considered the standard for encrypting messages, because at the time this video was recorded, it's never been cracked. PGP was purchased a while ago and commercialized. It's owned by NortonLifeLock, formally known as Symantec, and provides products that can protect all sorts of devices, even smartphones.
In response to PGP becoming a commercial product, GNU Privacy Guard was created in 1999. GPG is a command line utility that's used to encrypt and decrypt data and messages. GPG functions just like PGP. It uses both symmetric and asymmetric keys to encrypt and secure data and messages.
To generate a random session key, the user performs actions on the computer, such as typing on the keyboard or moving the mouse. This helps to ensure that the key is truly random.
Because it's an open-sourced utility, GPG can be used on many different systems, including Windows, Linux, Android, and Apple's OS X.
That wraps up this lesson. In this video, we looked at two popular utilities for encrypting files and messages, Pretty Good Privacy and GNU Privacy Guard. Both utilities use a hybrid cryptographic model and are very secure. The biggest difference between them is that PGP is a commercial product, and GPG is a free open-source utility.

3.4.5 Encrypting Files with GPG (Demo Video)

Transcript:

In this demonstration, we're going to review how to encrypt files on a Linux system using GPG. The GPG utility is the open-source equivalent of the PGP utility.

First, we need to verify that GPG's installed on the system, so we're going to type â€˜gpg â€“version'. As you can see here, it'll show us the version information. It wouldn't show this if GPG wasn't installed. Most Linux distributions should have this installed by default. It's currently installed on the system. Let's go ahead and clear our screen.

Now we need to generate a key pair. To do that, we're going to type â€˜gpg --gen-key'. If you want to have more customization, you can use the full-featured key generation dialog as listed. It wants to know the real name. We're just going to put our username in this field, rmckay. Our email address is rmckay@testout.com. This last menu wants us to verify the information. We'll okay it.
Another dialog box will come up asking us to enter a passphrase. For this demo, I'm just going to use the word â€˜TestOut'. This gives us a warning, saying it's an unsecure passphrase. Normally, you would make this password more secure, but for now, we're going to leave it as-is. We'll re-enter the same passphrase. Now our public and secret keys are created.
We're going to encrypt an example file in our Home directory. It's called example.txt. We can see this by doing an â€˜ll' to list the directory.
Now we want to go ahead and encrypt our file using GPG. You don't have to specify the entire directory path of the file if you're in the directory where the file exists.
To encrypt, we're going to type in â€˜gpg -e example.txt' and then the name that we created, â€˜rmckay'. Then we're going to click Enter twice, as there's no more information we need to add.
Now, if we type â€˜ll' and look, we can see the original example.txt, and we can see the encrypted version of example.txt.gpg. If we use the CAT command to view this encrypted version of the file, you can see that it's all scrambled. Clearly, we can't read the file or tell what it says. At this point, obviously, we need to decrypt this file before we can read it. That's what we're going to do next. I'm just going to clear the screen again.
Now, we're going to type â€˜gpg â€“output'. We're going to follow this with the file name for the new decrypted file that we're going to create, â€˜example.txt.decrypted'. Okay. Now we're going to do â€˜--decrypt example.txt.gpg'.
In this case, we're decrypting with the same user we created a public and private key with, so it won't prompt us for a password. Okay. Now we can use â€˜ll' to list the files. We see our decrypted file right here. If we use the CAT command, we see what's inside example.txt.decrypted. This verifies that the GPG utility successfully decrypted the file.
That's it for this demonstration. We discussed how to encrypt and decrypt files in a Linux system using GPG.

3.4.6 BitLocker and Database Encryption (Lesson Video)

Transcript:

Organizations often store sensitive data on devices and in databases. Implementing proper data encryption is key to securing this sensitive data. Using BitLocker and proper database encryption can help protect data if a physical device, such as a laptop, is stolen or if a hacker gains access to a database.

A lost or stolen computer can be catastrophic to an organization if it holds confidential information. With the release of Windows Vista, Microsoft introduced BitLocker to address this concern. BitLocker is a powerful encryption tool that, instead of encrypting individual files and folders, encrypts an entire volume, including operating system files. BitLocker is designed to protect data from unauthorized access, even if the drive is moved to another computer.
It's important to note that BitLocker isn't available on Home editions of Windows.
To implement BitLocker on a computer, the hard disk must be partitioned with two volumes. The system, or boot, volume contains the Windows boot files and is created during Windows installation. The standard volume contains all other data. The system volume won't be encrypted, but the standard volume will be.
One of the newer features of BitLocker in Windows 10 is the ability to only encrypt used space. This makes the encryption process so much faster. Previously, the entire drive, even space not in use, was encrypted. This process could take hours depending on the size of the drive.
BitLocker can also use the computer's Trusted Platform Module, or TPM, chip to verify the integrity of the system's boot files as long as the chip is at least version 1.2. It does this by encrypting the boot files and stores the encryption key in the TPM chip. When you log in to Windows, BitLocker automatically unlocks the encrypted drive. If the drive is moved to another computer, the encryption key won't match up, and the drive can't be accessed. It's possible to configure BitLocker to protect the system files without having a TPM chip, but you have to insert a startup USB key or have a system volume password enabled to boot into Windows.
When BitLocker is enabled, Windows creates the recovery key. This randomly generated key will be used if the hard drive needs to be moved to a different system, if changes are made to the startup files, or if BitLocker goes into a locked state and needs to be accessed. The recovery key is different from the user-generated password created during the configuration process.

Obviously, this is an incredibly important key. Windows gives you the option to save the key to your Microsoft Account, a USB flash drive, or a file on the local computer. You can also print the key out, and if you're on a domain, you can store the key in Active Directory. It's a good idea to back up this key multiple ways and then store it safely locked.
If you're on a domain, there are additional options for recovering data if the user password is lost. Using the stored recovery key would be the first and easiest option, especially if the key was stored in Active Directory. If the key can't be found, a Data Recovery Agent, or DRA, can be used. The DRA is just another account that has rights to decrypt the drive. This option must first be configured in Group Policy. If the hard drive contains the OS files, it'll need to be installed in another system as a data drive before the DRA can decrypt it.
When implemented properly, BitLocker is a powerful tool that can be used to protect data in case a laptop or other device that contains sensitive information is stolen or lost.
Many organizations store important sensitive data, such as customer billing information, in databases. Keeping this data encrypted helps protect it if a hacker ever gains access to the database.
The three main methods of database encryption are transparent, column-level, and application-level. Before we look at these methods in detail, let's review the structure of a database.
Databases are made up of multiple tables that use columns and rows filled with data. For example, we might have a table labeled Customers. In that table, we have columns labeled Name, Number, Email, and Address. The rows in each column are filled with the pertinent information.
Transparent data encryption, or TDE, encrypts the entire database and all backups. TDE is used for data at rest--data that's not in current use. This method is called transparent encryption because when an authorized user needs to access the data, it's automatically decrypted, so the user doesn't see the process or need to do anything extra.
Column-level encryption allows the administrator to encrypt each column using different keys. This increases security because multiple encryption keys are required to access all of the data. Keep in mind that this method does slow the database's performance.
In application-level encryption, the program that's used to create or modify the data is responsible for encrypting the data. This works well because the data is encrypted before it even hits the database. The drawback of this method is that the amount of resources required for setup can be prohibitive.
When an organization maintains sensitive data, they need to ensure that it's kept safe. Any of the methods in this video will help keep databases secure.
That wraps up this lesson. We've covered some solutions for encrypting sensitive data. BitLocker can be used to encrypt an entire hard drive or volume, which will prevent access if a device is stolen. And there are several methods an organization can use to encrypt sensitive data that's stored in databases.

3.4.7 Configuring BitLocker (Demo Video)

Transcript:

In this demonstration, we're going to show you how to use BitLocker to encrypt a drive on Windows. Before anything else, you should know that BitLocker isn't available unless you have Windows Professional version or higher. Home version doesn't support this feature. That being said, let's go to the Start menu and type bitlocker. Clicking Manage BitLocker brings up the settings we want. Now, the first thing we have to cover in order to understand the BitLocker setup is a TPM.

The TPM, or Trusted Platform Module, is a chip on the motherboard that's known as a cryptographic module. Basically, it's what stores your BitLocker keys. Without the TPM, you'd have to enter a long recovery key each time, especially if the BitLocker drive were installed on a computer other than the original one. It used to be common for motherboards to ship without a TPM, but as security has progressed, they're on pretty much every motherboard nowadays. In fact, a TPM is actually required with the latest versions of Windows.
Okay, let's move on. Look at the TPM Administration down here. This is an area that I'd highly suggest checking first before you consider BitLocker for your system. The TPM needs to be in a ready for use status and enabled in the UEFI or BIOS. If it was previously used for BitLocker, you may have to clear the TPM chip before using it. This system we have here hasn't been encrypted before, so we don't need to do that. Also, if it isn't in a ready for use status, you'll need to use this Prepare the TPM option up here. Let's close this Window.
To start the process, we need to click Turn on BitLocker. First, it'll ask us how we want to back up our recovery key. You have a few options, but we're just going to use Save to a file. When saving to a file, you're supposed to put this key on something else other than the drive being encrypted, usually something like a flash drive or network drive. We have a

flash drive as drive letter E: that we can use to store this. After selecting the drive and clicking Save, it tells us that our recover key has been saved. Were able to select Next.
Here we have options to encrypt just the used disk space or encrypt the entire drive. Typically, the Encrypt whole drive option takes longer because it doesn't care if space is used or not. This PC happens to be new, so we'll just choose Encrypt used disk space only. Okay, click Next.
Now, Microsoft introduced a new type of encryption method with the most recent versions of Windows. We could use it, but for now, we'll just leave it set to New encryption mode. Click Next.
The last part asks if you're ready to encrypt. I like to select the Run BitLocker system check just in case something ends up causing problems. In most cases, BitLocker deployment should go fine, but there are instances where it doesn't work properly. It's a good idea to have your computer backed up in some way so that your data can't be lost forever during this process. Click Continue.
Now we're ready to restart the computer. You'll get a pop up that lets you know a restart is required before you can keep going with the encryption. I'm going to reboot this computer and pause the recording.
Alright, after the restart, we see an option down in our taskbar that shows us that the drive is encrypting. When we click on it, it gives us a percentage of where it's at. Let's pause the recording again while this finishes.
Great! Our encryption is now done, and we're ready to go. Just to show you some options you have after the encryption is complete, let's go back. You can click Manage BitLocker, or you can access it like before through the Start menu.
The first option we have is Suspend protection, which means it'd put BitLocker on hold from securing your system. This might be good if Windows updates are needed and your PC is already secured with a BitLocker PIN. Make note that the BitLocker PIN won't be enabled unless you modify Group Policy and turn it on. That adds an extra layer of security, so it's definitely something to consider. Now, this isn't the same as a recovery key, as the recover key is typically 48 digits and is used as a last resort to decrypt your drive. Backup your recover key gives us the same box we had before, remember the Azure AD, Save to file, and Print options from earlier? And the last one is Turn off BitLocker. This process will take nearly the same amount of time to decrypt since it has to undo all the changes made during encryption.
That's it for this demonstration on BitLocker. In this video, we talked about how to encrypt a system drive. First, we looked at the TPM and the purpose that it serves in the BitLocker process. Then we discussed which settings you have available after BitLocker has successfully encrypted a drive.

3.4.8 Configure BitLocker with a TPM (Simulation)

Scenario

You work as the IT security administrator for a small corporate network. The employee in Office 1 is working on a very sensitive project. Management is concerned that if the hard drive in the computer were stolen, sensitive information could be compromised. As a result, you have been asked to encrypt the entire System volume. The Office 1 computer has a built-in TPM on the motherboard.

In this lab, your task is to configure BitLocker drive encryption as follows:

- From within the computer's BIOS, turn on and activate TPM Security.
- From Windows, turn on BitLocker for the System (C:) drive.
- Back up the recovery key to the **\\CorpServer\BU-Office1** folder.
- Encrypt the entire System (C:) drive.
- Use the new encryption mode.
- Run a BitLocker system check.

Explanation

Complete this lab as follows:

1. (Optional) Try to enable BitLocker.
    a. From the taskbar, select **Search** .
    b. In the Search field, type **Control**
    c. From *Best match* , select **Control Panel** .

d. Select **System and Security** .
e. From the right pane, select **BitLocker Drive Encryption** .
f. Under *Operating system drive* , select **Turn on BitLocker** .
An error message at the bottom of the screen indicates that a TPM security device was not found.
g. Select **Cancel** .

2. Access the BIOS settings.
a. Right-click **Start** , then select **Shut down or sign out** > **Restart** to reboot your computer.
b. When the TestOut logo appears, press **Delete** or **F2** to enter the BIOS.
3. Turn on and activate the TPM.
a. From the left pane, expand and select **Security** > **TPM Security** .
b. Select **TPM Security** and then select **Apply** .
c. Select **Activate** and then select **Apply** .
d. Select **Exit** .
Your computer will automatically reboot.
4. Turn BitLocker on.
a. From the taskbar, select **Search** .
b. In the Search field, type **Control**
c. From *Best match* , select **Control Panel** .
d. Select **System and Security** .
e. Select **BitLocker Drive Encryption** .
f. Under *Operating system drive* , select **Turn on BitLocker** .
Windows begins the Drive Encryption setup.
5. Back up a BitLocker recovery key.
a. Select **Save to a file** .
b. From the left pane, expand and select **Network** > **CorpServer** > **BU-Office1** .
c. Select **Save** .
d. Select **Next** .
6. Configure BitLocker encryption.
a. Select **Encrypt entire drive** and then select **Next** .
b. Make sure that **New encryption mode** is selected and then select **Next** .
c. Select **Run BitLocker system check** and then select **Continue** .
d. Select **Restart now** .
The computer will reboot, and the encryption process will run automatically.
e. When the encryption process is complete, select **Close** .
7. Verify that encryption is enabled.
a. From the Windows taskbar, select **File Explorer** .
b. From the left pane, select **This PC** .
c. From the right pane, verify that the **System (C:)** drive shows the *encryption lock* icon.

3.4.9 File Encryption Facts

Encryption of files, directories, and hard drives provides an additional level of data security. File encryption is part of a layered defense strategy and helps to protect confidential data in the event that system data is hacked, lost, or stolen. There are different methods that can be used to encrypt data or entire hard drives.

This lesson covers the following topics:

- Encryption supporting confidentiality
- Disk and file encryption
- Transport encryption and key exchange
- Encrypting File System (EFS)
- PGP and GPG
- BitLocker

Encryption Supporting Confidentiality

If data is encrypted, it does not matter if the disk storing the information is stolen or if it can be intercepted when transferred over a network because the threat actor will not be able to understand or change what has been stolen. This use of encryption fulfills the goal of confidentiality.

When deploying a cryptographic system to protect data assets, consideration must be given to how information could potentially be intercepted. Data can be described as being in one of three states:

- **Data at rest** - is the state when the data is in some sort of persistent storage media.
- **Data in transit (or data in motion)** - is the state when data is transmitted over a network.
- **Data in use (or data in processing)** - is the state when data is present in volatile memory, such as system RAM or CPU registers and cache.

Encrypting megabytes or gigabytes of data is referred to as bulk encryption. Asymmetric encryption and private/public key pairs are not often used for bulk encryption because an asymmetric algorithm cannot process large amounts of data efficiently. The computational overhead is too high when using this type of algorithm to encrypt the contents of a disk or series of network packets.

Therefore, bulk data encryption uses a symmetric cipher, such as AES. A *symmetric cipher* can encrypt and decrypt data files and streams of network traffic quickly. The problem is that distributing a symmetric key is challenging. The more people who know the key value, the weaker the confidentiality property is. Luckily, symmetric keys are only 128 or 256 bits long and can easily be encrypted using a public key. Consequently, most data encryption systems use both symmetric and asymmetric encryption in the following sort of scheme:

- The user generates an asymmetric key pair for the chosen cipher, such as RSA or ECC. The private key portion of this is encrypted so the user must supply their account credential to use it. In this context, the private key is the key encryption key (KEK).
- The system generates a symmetric secret key for the chosen cipher, such as AES256 or AES512. This is referred to as a file or media or data encryption key (DEK). This key is used to encrypt the target data.
- The data encryption key is then encrypted using the public key portion of the KEK.
- To access encrypted data, the user must supply a password or start an authenticated session to use their private key to decrypt the secret key, which can then decrypt the data.

Disk and File Encryption

Data at rest encompasses a great many storage mechanisms. These can be thought of in terms of encryption levels. Lower levels, such as encrypting a whole disk, have the advantage of simplicity but can be complex to manage when multiple users need to access the data. Higher levels, such as applying encryption via the file system or a database management system, can be combined with granular access controls.

Type	Description
Full-disk and partition encryption	Full-disk encryption (FDE) refers to a product that encrypts the whole contents of a storage device, including metadata areas not normally accessible using ordinary OS file explorer tools. FDE also encrypts free space areas. FDE primarily protects against physical theft of the disk. A stolen disk can be mounted on any computer, and the threat actor can take ownership of all the data files. This is not possible if the disk is encrypted because it must be unlocked by the user's credentials to access the decryption key. Many storage devices can perform self-encryption using a cryptographic product built into the disk firmware. A self-encrypting drive (SED) could be a hard disk drive (HDD), solid-state drive

Type	Description
	(SSD), or USB flash drive. The disk firmware implements a cryptoprocessor to store the keys so they are not directly exposed to the OS that mounts the disk. An HDD or SSD can be divided into separate logical areas called partitions. Each partition can be formatted with a different file system and mounted as a drive or volume in the OS. Some disk encryption products might be able to encrypt these partitions selectively rather than the whole disk. The partitions could be encrypted using different keys. For example, a disk could contain boot, system, and data partitions. The boot and system partitions could be left unencrypted as they contain only standard OS files, while the data partition is protected by encryption.
Volume and file encryption	A volume is any storage resource with a single file system. Put another way, a volume is how the OS "sees" a storage resource. The technology underlying the volume might be a removable disk or a partition on an HDD or SSD. It could also be a RAID array. Consequently, a volume encryption product is likely to refer to one that is implemented as a software application rather than by disk firmware. For example, while they might loosely be referred to as "disk encryption," Microsoft's BitLocker and Apple's FileVault products perform volume encryption. A volume encryption product may or may not encrypt free space and/or file metadata. A file encryption product is software that applies encryption to individual files (or perhaps to folders/directories). This might depend on file system support. For example, Microsoft's Encrypting File System (EFS) requires that the volume be formatted with NTFS. Metadata can include a list of files, the file owner, and created/last modified dates. Free or unallocated space can contain data remnants, where a file has been marked as deleted, but the data has not actually been erased from the storage medium. If the device has a TPM or an HSM compatible with the encryption product, the disk/volume/file system can be locked by keys stored in the TPM or HSM.
Database encryption	A structured database stores data in tables. Each table is composed of column fields with a given data type. Records are stored as rows in the table with a value entered for each field. The table data is ultimately stored as files on a volume, but access is designed to be mediated through a database management system (DBMS) running a database language such as Structured Query Language (SQL). Typically, the database is hosted on a server and accessed by client applications. The underlying files could be protected by a disk or volume encryption product running on the server. This will typically have an adverse impact on performance, so encryption is more commonly implemented by the DBMS or by a plug-in. Encryption can be applied at different granular levels. While each DBMS supports different features, the following encryption options, based on Microsoft's SQL Server DBMS, are typical.
Database-level encryption	Database- or page-level encryption and decryption occurs when any data is transferred between disk and memory. This is referred to as transparent data encryption (TDE) in SQL Server. A page is the means by which the database engine returns the data requested by a query from the underlying storage files. This type of encryption means that all the records are encrypted while stored on disk, protecting against theft of the underlying media. It also encrypts logs generated by the database.
Record-level encryption	Many databases contain secrets that should not be known by the database administrator. Public key encryption can solve this problem by storing the private key used to unlock the value of a cell outside of the database.

Type	Description
	Cell/column encryption is applied to one or more fields within a table. This can have less of a performance impact than database-level encryption, but the administrator needs to identify which fields need protection. It can also complicate client access to the data. The encryption/decryption mechanism can work in several ways, but with SQL Server's Always Encrypted feature, the data remains encrypted when loaded into memory. It is only decrypted when the client application supplies the key. The plaintext key is not available to the DBMS, so the database administrator cannot decrypt the data. This allows for the separation of duties between the database administrator and the data owner, which is important for privacy. Some solutions may additionally support record-level encryption. For example, a health insurer's database might store protected health information about its customers. Each customer could be identified by a separate key pair. This key pair would be used to encrypt data at a row/record level. The table contains records separately protected by different keys. This allows fine-grained control over how data can be accessed to meet compliance requirements for security and privacy.

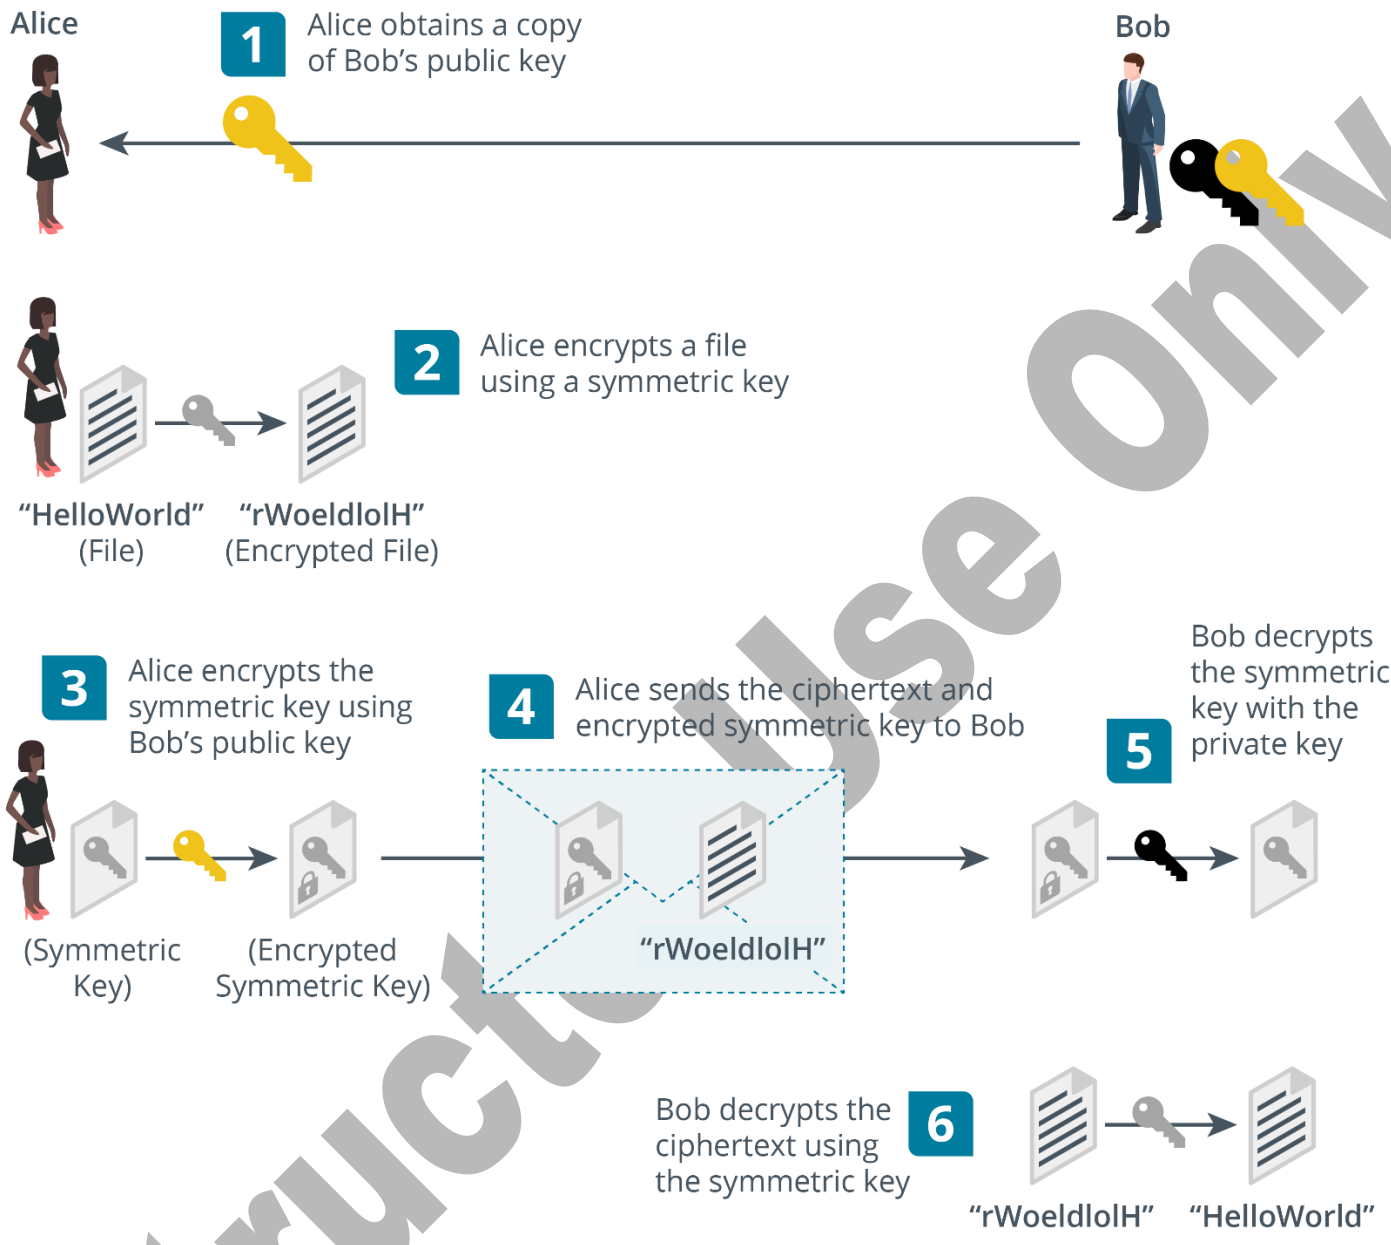
Transport Encryption and Key Exchange

Transport/communication encryption protects data in motion. Various transport encryption products have been developed for different networking solutions. Some examples include the following:

- **Wi-Fi Protected Access (WPA)** secures traffic sent over a wireless network.
- **Internet Protocol Security (IPsec)** secures traffic sent between two endpoints over a public or untrusted transport network. This is referred to as virtual private networking (VPN).
- **Transport Layer Security (TLS)** secures application data, such as web or email data, sent over a public or untrusted network.

As with data-at-rest, an asymmetric cipher is not typically used to encrypt the network data directly because it is too inefficient. Transport encryption products use a system of key exchange . This allows the sender and recipient to exchange a symmetric encryption key securely by using public key cryptography:

- Alice obtains a copy of Bob's RSA or ECC public key, typically via Bob's digital certificate.
- Alice encrypts their message using a secret key cipher, such as AES. In this context, the secret key is referred to as a *session key* .
- Alice encrypts the session key with Bob's public key.
- Alice attaches the encrypted session key to the ciphertext message in a digital envelope and sends it to Bob.
- Bob uses their private key to decrypt the session key.
- Bob uses the session key to decrypt the ciphertext message.



Key exchange using a digital envelope. (Images © 123RF.com.)

Transport encryption also uses cryptography to ensure the integrity and authenticity of messages so that the recipient can verify that they were not modified by someone other than the sender. Integrity and authenticity checking can use a hash-based Message Authentication Code (HMAC) . An HMAC combines the secret key derived during a key exchange with a hash of the message.

Alternatively, the symmetric cipher might be designed to perform Authenticated Encryption (AE). This type of symmetric cipher mode of operation ensures confidentiality and integrity/authenticity.

Encrypting File System (EFS)

The Encrypting File System (EFS) was introduced with NTFS version 3 and has been included in every version of Windows since Windows 2000 except for the Home editions. EFS provides an easy and seamless way for users to encrypt files on their Windows computers. EFS is only used to encrypt individual files and folders.

EFS combines the speed of symmetric encryption with the convenience of asymmetric encryption using a process called key encapsulation. The process for a user to encrypt a file is as follows:

1. The user accesses Properties and, from the General tab, clicks **Advanced** . From there, the user selects Encrypt contents to secure data.
2. Windows generates a pseudo-random number called the file encryption key (FEK). Windows uses the FEK with the AES encryption algorithm to encrypt the file.
3. The FEK is then encrypted using the user's public key. The encrypted FEK is stored in the file's header in a special location called the Data Decryption Field (DDF).
4. The decryption process is the opposite. The user's private key is used first to unlock the DDF and get the FEK. The FEK is then used to decrypt the file.

The encryption and decryption process relies on the user's password being kept safe. If the user account becomes corrupted or the password is forgotten, any encrypted files are lost. To help remedy this, a data recovery agent (DRA) can be set up. The DRA is simply another account that can decrypt the encrypted files.

- The DRA used to be automatically configured as the system administrator in older versions of Windows. Nowadays, it is no longer automatically set up.
- A local DRA for an individual workstation can be configured through the machine's Group Policy settings.
- A domain-wide DRA can be configured in Active Directory. Only a domain administrator can set up a domain-wide DRA.

Additional security considerations are:

- Decryption keys can be backed up to an external USB drive. This ensures access even if the Windows system completely crashes.
- A file is automatically unencrypted when moved or copied to a non-NTFS formatted device or media. A file is also automatically unencrypted when you copy a file over the network using the SMB Protocol.
- Key security relies on the user having a strong password and following proper password security protocols.

PGP and GPG

GNU Privacy Guard (GPG) is an encryption tool that encrypts emails, digitally signs emails, and encrypts documents. GPG is an implementation of the Pretty Good Privacy (PGP) Protocol. PGP is a commercial product now owned by Symantec and makes products that can be used to protect laptops, desktops, USB drives, optical media, and smartphones.

Both PGP and GPG do the following:

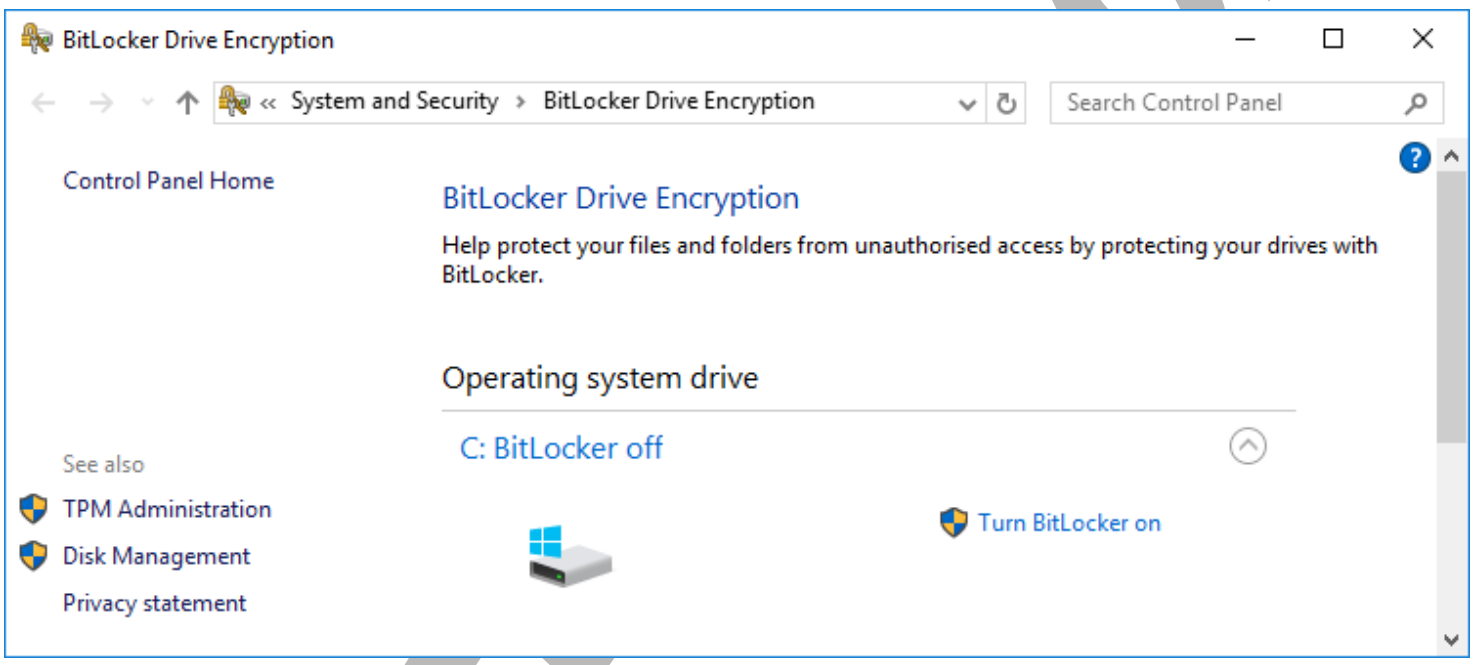
- Follow the OpenPGP standard (RFC 4880) for encrypting and decrypting data.
- Combine asymmetric and symmetric cryptography. The process is as follows:
    1. GPG/PGP generates a random symmetric key to encrypt the message.
    2. The symmetric key is then encrypted using the receiver's public key and sent along with the message.
    3. When the recipient receives a message, GPG/PGP first decrypts the symmetric key with the recipient's private key.
    4. The decrypted symmetric key is then used to decrypt the rest of the message.

GPG supports many common algorithms, including RSA, DSA, 3DES, IDEA, MD5, SHA, and more. AES is used by default. PGP can use either RSA or the Diffie-Hellman algorithm for asymmetric encryption and IDEA for symmetric encryption.

BitLocker

Full disk encryption (FDE) means that the entire contents of the drive (or volume), including system files and folders, are encrypted. OS ACL-based security measures are quite simple to circumvent if an adversary can attach the drive to a different host OS. Drive encryption allays this security concern by making the contents of the drive accessible only in combination with the correct encryption key. Disk encryption can be applied to hard disk drives (HDDs) and solid state drives (SSDs).

FDE requires the secure storage of the key used to encrypt the drive contents. Normally, this is stored in a Trusted Platform Module (TPM). The TPM chip has a secure storage area with a disk encryption program, such as Windows BitLocker, to which it can write its keys. It is also possible to use a removable USB drive (if USB is a boot device option). As part of the setup process, you create a recovery password or key. This can be used if the disk is moved to another computer or the TPM is damaged.



Activating BitLocker drive encryption. (Screenshot used with permission from Microsoft.)

One of the drawbacks of FDE is that because the OS performs the cryptographic operations, performance is reduced. This issue is mitigated by self-encrypting drives (SED) , where the cryptographic operations are performed by the drive controller. The SED uses a symmetric data/media encryption key (DEK/MEK) for bulk encryption. It stores the DEK securely by encrypting it with an asymmetric key pair called the authentication key (AK) or key encryption key (KEK) . The use of the AK is authenticated by the user password. This means that the user password can be changed without having to decrypt and re-encrypt the drive. Early types of SEDs used proprietary mechanisms, but many vendors now develop using the Opal Storage Specification (nvmexpress.org/wp-content/uploads/TCGandNVMe_Joint_White_Paper-TCG_Storage_Opal_and_NVMe_FINAL.pdf), developed by the Trusted Computing Group (TCG).

3.4.10 Practice Questions (Section Quiz)

q_file_encryption_confident_secp8

You create a new document and save it to a hard drive on a file server on your company's network. Then you employ an encryption tool to encrypt the file using AES.

This activity is an example of accomplishing which security goal?

Answers:

- ***Confidentiality**
- Integrity
- Availability
- Non-repudiation

Explanation:

Encrypting a file while it is stored on a hard drive is usually done to provide protection for the object's confidentiality.

Hashing is used to provide integrity.

Using mechanisms like backups and avoiding single points of failure provide availability protection.

Non-repudiation is usually provided for during a secured communication, not while a file is stored on a hard drive.

q_file_encryption_dra_secp8

Which of the following should you set up to ensure encrypted files can still be decrypted if the original user account becomes corrupted?

Answers:

- PGP
- VPN
- ***DRA**
- GPG

Explanation:

If a user account becomes corrupted or the password is forgotten, any encrypted files are lost. To help remedy this, a data recovery agent (DRA) can be set up. The DRA is simply another account that can decrypt the encrypted files.

Pretty Good Privacy (PGP) is an older utility used to encrypt and decrypt data and messages.

A virtual private network (VPN) uses an encryption protocol (such as IPsec, PPTP, or L2TP) to establish a secure communication channel between two hosts or between one site and another site.

GNU Privacy Guard (GPG) is a command line utility that's used to encrypt and decrypt data and messages.

q_file_encryption_encrypt_01_secp8

You want a security solution that protects the entire hard drive and prevents access even if the drive is moved to another system.

Which solution should you choose?

Answers:

- EFS
- VPN

- IPsec
- ***BitLocker**

Explanation:

BitLocker is a Microsoft security solution that encrypts the entire contents of a hard drive, protecting all files on the disk. BitLocker uses a special key that is required to unlock the hard disk. You cannot unlock/decrypt a drive simply by moving it to another computer.

EFS is a Windows file encryption option, but it only encrypts individual files. Encryption and decryption is automatic and dependent upon the file's creator and whether other uses have read permissions.

A virtual private network (VPN) uses an encryption protocol (such as IPsec, PPTP, or L2TP) to establish a secure communication channel between two hosts or between one site and another site. Data that passes through the unsecured network is encrypted and protected.

q_file_encryption_encrypt_02_secp8

Which of the following security solutions would prevent a user from reading a file that they did not create?

Answers:

- ***EFS**
- Bitlocker
- VPN
- IPsec

Explanation:

EFS is a Windows file encryption option that encrypts individual files so that only the user who created the file can open it. Decryption is automatic when the file owner opens it. Other users cannot open the encrypted file unless specifically authorized.

BitLocker is a Microsoft security solution that encrypts the entire contents of a hard drive, protecting all files on the disk. BitLocker uses a special key that is required to unlock the hard disk. You cannot unlock/decrypt a drive simply by moving it to another computer.

A virtual private network (VPN) uses an encryption protocol (such as IPsec, PPTP, or L2TP) to establish a secure communication channel between two hosts or between one site and another site. Data that passes through the unsecured network is encrypted and protected.

q_file_encryption_encrypt_03_secp8

You've used BitLocker to implement full volume encryption on a notebook system. The notebook motherboard does not have a TPM chip, so you've used an external USB flash drive to store the BitLocker startup key.

You use EFS to encrypt the C:\Secrets folder and its contents.

Which of the following is true in this scenario? (Select two.)

Answers:

- ***If the C:\Secrets\confidential.docx file is copied to an external USB flash drive, the file will be saved in an unencrypted state.**
- ***By default, only the user who encrypted the C:\Secrets\confidential.docx file will be able to open it.**
- Any user who is able to boot the computer from the encrypted hard disk will be able to open the C:\Secrets\confidential.docx file.
- The EFS encryption process will fail.
- Only the user who encrypted the C:\Secrets\confidential.docx file is able to boot the computer from the encrypted hard disk.
- If the C:\Secrets\confidential.docx file is copied to an external USB flash drive, the file will remain in an encrypted state.

Explanation:

BitLocker uses full volume encryption, while EFS is used to encrypt individual files and folders. The following are true in this scenario:

- If the C:\Secrets\confidential.docx file is copied to an external USB flash drive, the file will be saved in an unencrypted state.
- Only the user who encrypted the C:\Secrets\confidential.docx file will be able to open it by default.

With BitLocker enabled, any user who has the appropriate startup key or PIN is able to boot the system from the encrypted drive. However, only the user who encrypted the C:\Secrets\ folder will be able to access files within it unless additional user accounts are explicitly added.

q_file_encryption_ipsec_secp8

Which utility would you MOST likely use on OS X to encrypt and decrypt data and messages?

Answers:

- PGP
- ***GPG**
- VPN
- IPsec

Explanation:

GNU Privacy Guard (GPG) is a command line utility that's used to encrypt and decrypt data and messages. GPG is a open source utility and can be used on many different systems, including Windows, Linux, Android, and Apple's OS X.

Pretty Good Privacy (PGP) is an older utility used to encrypt and decrypt data and messages. PGP was purchased a while ago and commercialized. It's owned by NortonLifeLock, formally known as Symantec, and provides products that can protect all sorts of devices, even smartphones. While PGP can be used on OS X, GPG is used by default.

A virtual private network (VPN) uses an encryption protocol (such as IPsec, PPTP, or L2TP) to establish a secure communication channel between two hosts or between one site and another site. A VPN is not used on OS X to encrypt and decrypt data and messages.

IPSec is a protocol used to encrypt VPN communication.

q_file_encryption_pgp_gpg_secp8

Which of the following statements about GPG (GNU Privacy Guard) and PGP (Pretty Good Privacy) is true?

Answers:

- GPG is a proprietary version of PGP.
- GPG and PGP use only symmetric encryption.
- GPG and PGP are incompatible and cannot interoperate.
- ***Both GPG and PGP can be used for encrypting, decrypting, and signing data.**

Explanation:

Both GPG and PGP can be used for encrypting and decrypting data to maintain confidentiality, and for signing data to ensure integrity and authenticity.

GPG is not a proprietary version of PGP. It is an open-source version of PGP.

GPG and PGP use a combination of symmetric and asymmetric encryption, not just symmetric encryption.

GPG and PGP are interoperable. They can work together because they follow the OpenPGP standard.

q_file_encryption_tpm_01_secp8

You would like to implement BitLocker to encrypt data on a hard disk, even if it is moved to another system. You want the system to boot automatically without providing a startup key on an external USB device.

What should you do?

Answers:

- ***Enable the TPM in the BIOS.**
- Disable USB devices in the BIOS.
- Use a PIN instead of a startup key.
- Save the startup key to the boot partition.

Explanation:

When a system boots, the startup key is required to unlock the encrypted volume. The system startup key can be saved in the Trusted Platform Module (TPM). With the startup key saved in the TPM, the system can start without additional intervention.

The system will not start without the startup key. Without a TPM, the startup key must be stored on a USB drive.

You can require a PIN in addition to a startup key, but the PIN cannot replace the startup key.

Storing the startup key on the boot drive would expose it to compromise.

q_file_encryption_tpm_02_secp8

You want to protect data on hard drives for users with laptops. You want the drive to be encrypted, and you want to prevent the laptops from booting unless a special USB drive is inserted. In addition, the system should not boot if a change is detected in any of the boot files.

What should you do?

Answers:

- Implement BitLocker without a TPM.
- ***Implement BitLocker with a TPM.**
- Have each user encrypt user files with EFS.
- Have each user encrypt the entire volume with EFS.

Explanation:

If you use BitLocker without a TPM, system integrity checks are not performed. The TPM is required for saving the startup file information that is used to verify system integrity. When using BitLocker without a TPM, you must use a startup key on a USB device. When using a TPM, this is an optional configuration.

Use BitLocker to encrypt the entire system volume and protect both operating system and user data. Use BitLocker with a Trusted Platform Module (TPM) to protect the boot environment components such as the BIOS, Master Boot Record, Boot Sector, Boot Manager, and Windows Loader. The system is shut down if a boot environment change is detected. Using BitLocker, drives are locked if they are moved to another computer, and you can require a startup key on a USB drive or a PIN before the system boots.

EFS encrypts individual files. With EFS, only the user who encrypted the file and any additionally designated users can access the file. EFS does not provide integrity checks for boot files.

q_file_encryption_trans_data_secp8

Which of the following database encryption methods encrypts the entire database and all backups?

Answers:

- ***Transparent Data Encryption (TDE)**
- Column-level
- Application-level
- Bitlocker

Explanation:

Transparent Data Encryption (TDE) encrypts the entire database and all backups. TDE:

- encrypts data at rest, which is data not being currently used.
- is called transparent because when an authorized user needs to access the data, it is automatically decrypted so the user does not see the process or need to do anything extra.

Column-level encryption allows the administrator to encrypt each column separately.

In application-level encryption, the program that is used to create or modify the data is responsible for encrypting the data.

BitLocker is a Microsoft security solution that encrypts the entire contents of a hard drive, protecting all files on the disk.

q_file_encryption_unencrypt_secp8

You have transferred an encrypted file across a network using the Server Message Block (SMB) Protocol.

What happens to the file's encryption?

Answers:

- The encryption carries over to the new location.
- The encryption inherits from the new location.
- An encrypted file cannot be moved using SMB.
- ***The file is unencrypted when moved.**

Explanation:

A file is automatically unencrypted when you copy it over a network using the SMB Protocol.

The encryption does not carry over to the new location, nor does the file inherit from the new location.

A file can be moved using the SMB Protocol.

3.5 Public Key Infrastructure

As you study this section, answer the following questions:

- What is the lifecycle of an encryption key?
- What is the role of a certificate authority (CA)?
- What are the types of certificates?
- Which standard defines the format of certificates?
- Which trust model would be used to connect the CAs of two organization's?

In this section, you will learn to:

- Manage certificates.

The key terms for this section include:

Term	Definition
Public key infrastructure (PKI)	A framework of certificate authorities, digital certificates, software, services, and other cryptographic components deployed for the purpose of validating subject identities.
Third party CAs	In PKI, a public CA that issues certificates for multiple domains and is widely trusted as a root trust by operating systems and browsers.
Digital certificate	Identification and authentication information presented in the X.509 format and issued by a certificate authority (CA) as a guarantee that a key pair (as identified by the public key embedded in the certificate) is valid for a particular subject (user or host).
Public Key Cryptography Standards (PKCS)	A series of standards defining the use of certificate authorities and digital certificates.

Certificate signing request (CSR)	A Base64 ASCII file that a subject sends to a CA to get a certificate.
Common name (CN)	An X500 attribute expressing a host or username, also used as the subject identifier for a digital certificate.
Subject alternative name (SAN)	A field in a digital certificate allowing a host to be identified by multiple host names/subdomains.
Wildcard	In PKI, a digital certificate that will match multiple subdomains of a parent domain.
Certificate revocation list (CRL)	A list of certificates that were revoked before their expiration date.
Online Certificate Status Protocol (OCSP)	Allows clients to request the status of a digital certificate, to check whether it is revoked.
Root certificate	In PKI, a certificate authority that issues certificates to intermediate certificate authorities in a hierarchical structure.
Certificate chaining/Chain of trust	A method of validating a certificate by tracing each CA that signs the certificate up through the hierarchy to the root CA.
Self-signed certificate	A digital certificate that has been signed by the entity that issued it, rather than by a certificate authority.
Escrow	In key management, the storage of a backup key with a third party.

This section helps you prepare for the following certification exam objectives:

Exam	Objective

CompTIA Security+ SY0-701	1.4 Explain the importance of using appropriate cryptographic solutions.
	• Public key infrastructure (PKI)
	  ○ Public key
	  ○ Private key
	  ○ Key escrow
	• Digital signatures
	• Certificates
	  ○ Certificate authorities

	○ Certificate revocation lists (CRLs) ○ Online Certificate Status Protocol (OCSP) ○ Self-signed ○ Third-party ○ Root of trust ○ Certificate signing request (CSR) generation ○ Wildcard 4.1 Given a scenario, apply common security techniques to computing resources. • Application security ○ Input validation ○ Secure cookies ○ Static code analysis ○ Code signing
TestOut Security Pro	4.2 Implement Encryption Technologies 4.2.3 Manage Certificates

3.5.1 Public Key Infrastructure (Lesson Video)

Transcript:

When we encrypt data over the internet, we generally utilize asymmetric encryption methods that involve sending a user's public key to provide confidentiality and trust. Because these keys are public, we need a way to manage and protect them.

Key management covers these keys' whole life cycle. During this cycle, we must keep keys safe because we need to be sure that the public key we're using really does belong to the organization it's associated with. Public key infrastructure, or PKI, handles this for us.
A PKI provides an environment where public encryption keys can be created and managed. At the heart of a PKI are Certificate Authorities, which are responsible for issuing, validating, and revoking certificates. In this lesson, I'll go over the concept of Certificate Authorities, or CAs, and the process they use to verify a certificate with all of its different attributes.
A PKI relies on certificates that validate organizations. This creates a web of trust across the internet, allowing us to perform transactions confidently with websites around the globe. A PKI requires several elements to be effective.
The first element is the CA. CAs need to be reputable organizations that are respected enough to issue public certificates to organizations that want to communicate securely over the internet.
To increase security, CAs operate in a hierarchy of multiple CAs. This is done so that if one CA is compromised, only the certificates it issued need to be revalidated.
The first CA is the Root CA. This is a self-signed certificate that's used to validate additional CAs.
These Subordinate CAs are also known as Intermediate CAs. We can have multiple Intermediate CAs based on their policies and regulations. The Intermediate CAs validate the Issuing certificate authorities, and the Issuing CA is the one that hands out the certificates.
Now that we understand the certificate authorities' hierarchy, let's look at how an organization can obtain their very own certificate.
To obtain a certificate, an organization needs to first send in a certificate signing request, or CSR, to a Certificate Authority. The CSR should contain the organization's public key, domain name, and digital signature. Then the CA verifies this information and issues the certificate.

When filling out the CSR, the organization provides their Common Name, or CN, which is more commonly referred to as the Fully Qualified Domain Name. For example, here you see that TestOut's Common Name would be www.testout.com.
The organization can also apply for a Subject Alternative Name, or SAN. This allows one certificate to apply to multiple host names. For example, TestOut could apply for a SAN that would cover site1.testout.com and site2.testout.com.
Once the CA has received the CSR, they verify the information and provide the certificate to the requesting organization.
Sometimes the CA relies on a third party to perform the validation. These third parties are called Registration Authorities. An RA is certified by a Root CA and is authorized to issue certificates for specific uses only. No matter who issues the certificates, each one has specific attributes for specific purposes.
Each CA's responsibility is to maintain a database that contains information on each certificate they've issued. This information is mainly their certificates' attributes.
These attributes contain everything from the serial number and signature algorithm to the public key and expiration date. CAs use the X.509 standard to define these attributes.
Each certificate has an expiration date. Before the certificate expires, the organization must revalidate the information and renew their certificate. If they don't, it's no longer valid.
Aside from expiration, there are other reasons a CA might invalidate or revoke a certificate. For example, if the organization is found to no longer exist, if the private key is compromised, or if the certificate was discovered to be fake, the CA should immediately revoke the certificate.
When a CA does revoke a certificate, it's added to a Certificate Revocation List, or CRL. This is a type of certificate blacklist. CAs maintain the CRL as part of their databases, and these should be updated quite often.
The X.509 standard also defines an internet protocol that can be used to determine a certificate's current state. This is called the Online Certificate Status Protocol, or OCSP.
The way OCSP works is your browser sends a status request to an OCSP responder and receives a response as to whether a certificate is valid or has been revoked.
Using the OCSP provides a few benefits. These include providing more timely information on a certificate's status, better bandwidth management because the client doesn't need to download the CRL, and a grace period for expired certificates.
If we follow the guidelines set in the X.509 standard, we can be assured that internet certificates are valid and have been checked appropriately by reputable Certificate Authorities.
That's it for this lesson. In this lesson, we covered Certificate Authorities and the hierarchical structure they're set up in. We also looked at the process an organization goes through to request a certificate for themselves. Finally, we looked at some certificate attributes and how CAs use them to validate certificates or put them on a Certificate Revocation List.

3.5.2 Public Key Infrastructure Facts

Public Key Infrastructure (PKI) is the framework that helps to establish trust in the use of public key cryptography to sign and encrypt messages via digital certificates. A digital certificate is a public assertion of identity validated by a certificate authority (CA).

This lesson covers the following topics:

- Certificate authorities
- Digital certificates
- Certificate attributes

Certificate Authorities

Public key cryptography solves the problem of distributing encryption keys when you want to communicate securely with others or authenticate a message that you send to others.

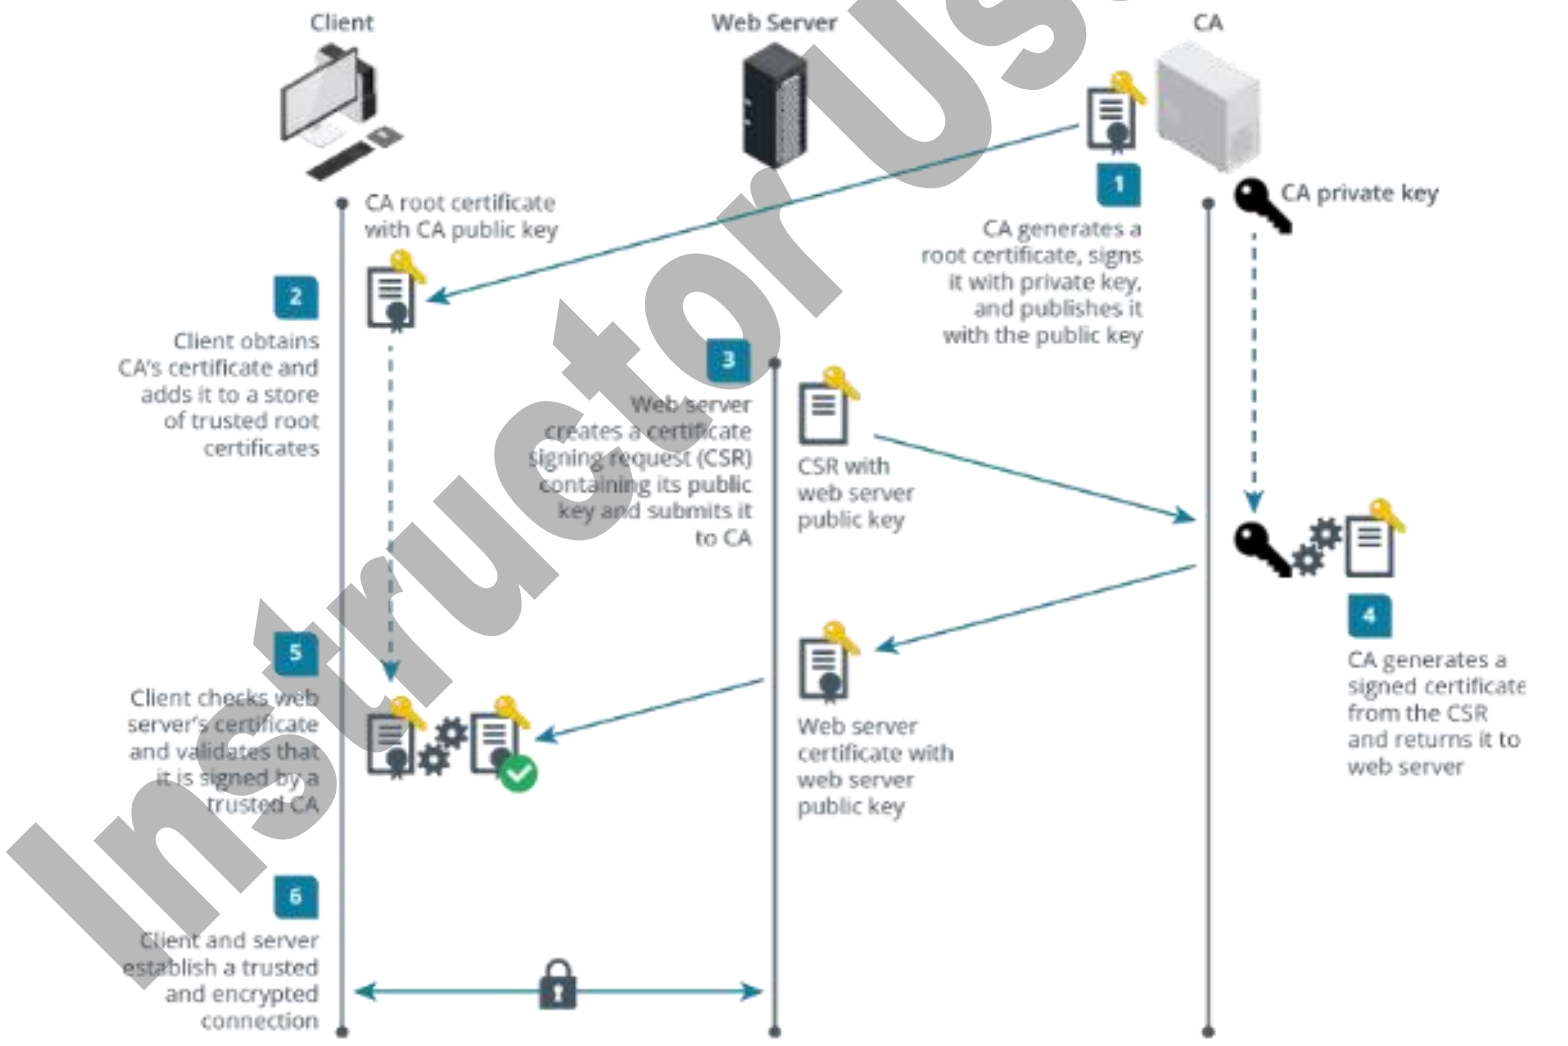
- When you want others to send you confidential messages, you give them your public key to encrypt the message. The message can then only be decrypted by your private key, which you keep known only to yourself.

- When you want to authenticate yourself to others, you sign a hash of your message with your private key. You give others your public key to use to verify the signature. As only you know the private key, everyone can be assured that only you could have created the signature.

The basic problem with public key cryptography is that while the owner of a private key can authenticate messages, there is no mechanism for establishing the owner's identity. This problem is particularly evident with e-commerce. How can you be sure that a shopping site or banking service is really maintained by whom it claims? The fact that the site is distributing a public key to secure communications is no guarantee of actual identity. How do you know that you are corresponding directly with the site using its genuine public key? How can you be sure there is no threat actor with network access intercepting and modifying what you think the legitimate server is sending you?

Public key infrastructure (PKI) aims to prove that the owners of public keys are who they say they are. Under PKI, anyone issuing a public key should publish it in a digital certificate. The certificate's validity is guaranteed by a certificate authority (CA).

PKI can use private or third-party CAs . A private CA can be set up within an organization for internal communications. The certificates it issues will only be trusted within the organization. For public or business-to-business communications, a third-party CA can be used to establish a trust relationship between servers and clients. Examples of third-party CAs include Comodo, DigiCert, GeoTrust, IdenTrust, and Let's Encrypt.



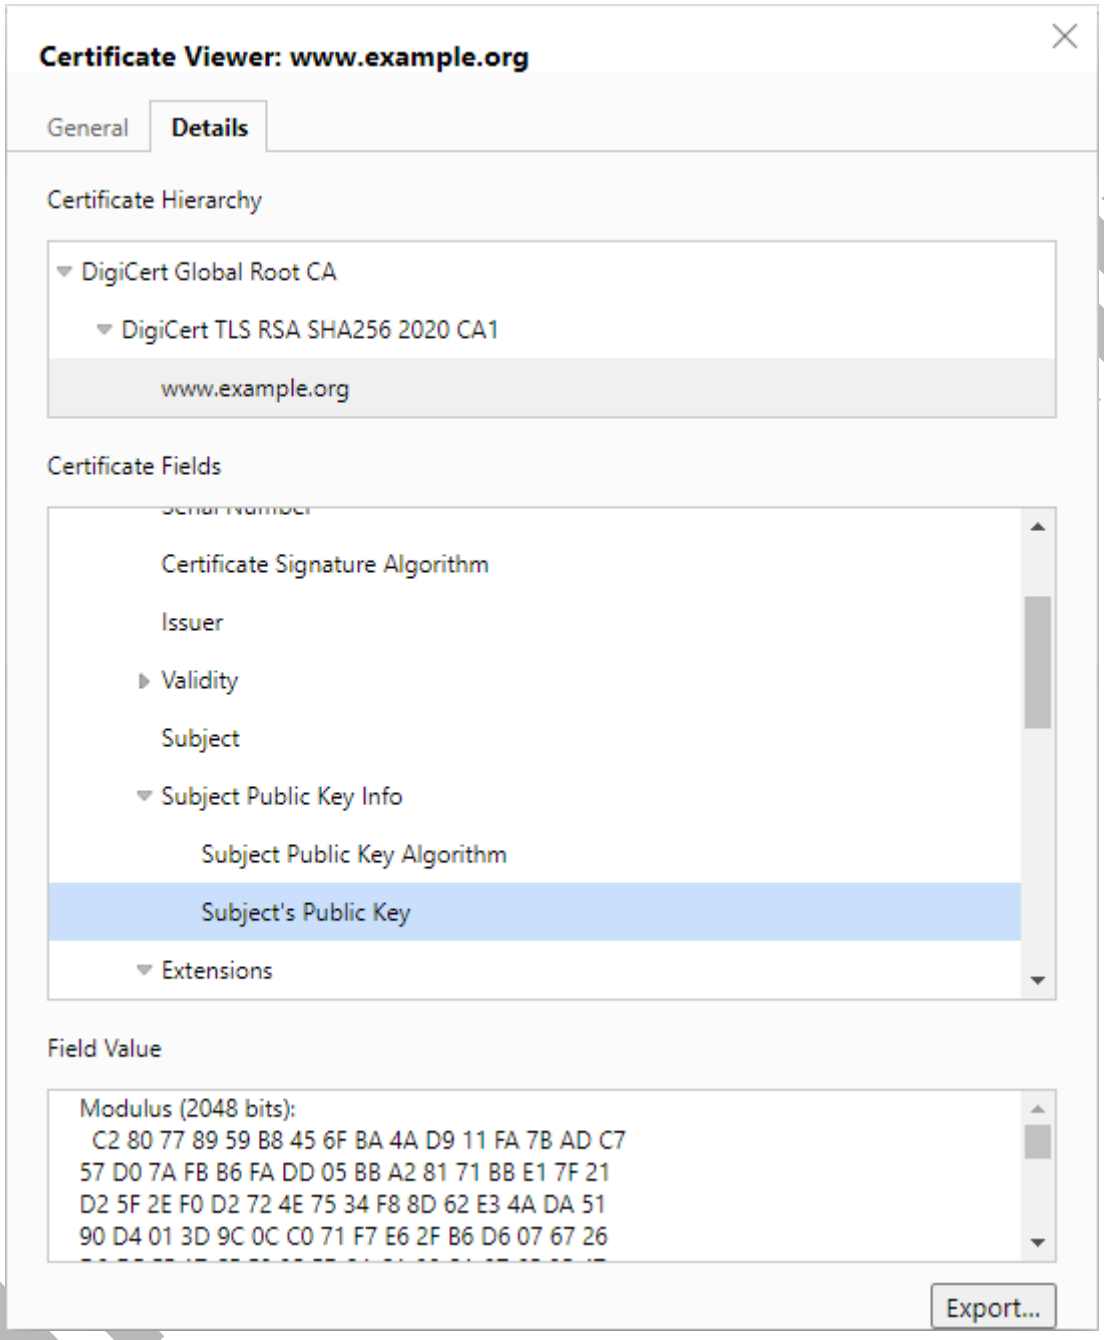
Public key infrastructure allows clients to establish a trust relationship with servers via certificate authorities.

The functions of a third-party public CA are as follows:

- Provide a range of certificate services useful to the community of users serviced by the CA.
- Ensure the validity of certificates and the identity of those applying for them (registration).
- Establish trust in the CA with users, governments, regulatory authorities, and enterprises such as financial institutions.
- Manage the servers (repositories) that store and administer the certificates.
- Perform key and certificate lifecycle management, notably revoking invalid certificates.

Digital Certificates

A digital certificate is essentially a wrapper for a subject's public key. As well as the public key, it contains information about the subject and the certificate's issuer. The certificate is digitally signed to prove that it was issued to the subject by a particular CA. The subject could be a human user (for certificates allowing the signing of messages, for instance) or a computer server (for a web server hosting confidential transactions, for instance).



Digital certificate details showing the subject's public key. (Screenshot used with permission from Microsoft.)

Digital certificates are based on the X.509 standard approved by the International Telecommunications Union and standardized by the Internet Engineering Task Force (tools.ietf.org/html/rfc5280). RSA also created a set of standards, referred to as Public Key Cryptography Standards (PKCS) , to promote the use of public key infrastructure.

Certificate Attributes

Each CA is responsible for maintaining a database containing the information or attributes of each certificate. The attributes that can be included are:

- Version - The X.509 version used for the certificate.
- Serial Number - A unique identifier for each certificate.
- Signature algorithm - The algorithm used to sign the certificate (SHA-2, RSA, etc.).
- Issuer - The CA that issues the certificate.
- Valid From and Valid To - The two fields that show the validity period of the certificate.
- Subject - The field that contains the name and location information of the organization.
- Public Key - The algorithm used to create the key and the public key information.

Depending on the organization, there may also be additional optional fields called extensions in the certificate.

One of the key attributes is the Valid To field. If a certificate is not renewed by this date, it will expire and no longer be valid. Aside from expiration, some other reasons a certificate might be invalidated are:

- The organization no longer exists.
- The private key has been compromised.
- The issued certificate is discovered to be fake.

If a certificate is invalidated for these or other reasons, it will be added to a certificate revocation list (CRL). The CRL is a blacklist of certificates. CAs must maintain and constantly update the CRLs as part of their databases. Web browsers automatically download updated CRLs at set intervals.

The X.509 standard also defines an internet protocol that can be used to determine the validity or state of a certificate. This is called the Online Certificate Status Protocol (OCSP). OCSP can be used to simplify the process of checking whether or not a certificate is valid.

OCSP is designed to replace CRLs. Instead of a CA maintaining the CRL, an OCSP server called a responder maintains the lists of any revoked certificate. When the browser connects to a site, the browser sends a request to the OCSP responder to check the validity of the certificate. OCSP provides the following benefits:

- Timely information on the status of a certificate.
- Better bandwidth management because the client does not download the entire CRL.
- A grace period for expired certificates.

3.5.3 Certificate Types (Lesson Video)

Transcript:

Depending on your purpose, there are different types of public key infrastructure certificates, or PKI certificates. These certificates are used to verify an organization's identity and ownership of the public key. In this lesson, I'll cover these types of certificates and how you can use them. I'll also go over some different validation levels used for SSL certificates.

A root certificate is the first certificate that a Certificate Authority, or CA, creates. This certificate is self-signed and is used to sign lower-level certificates, such as intermediate certificates. These certificates go through different processes to be approved, and the process depends on the certificate and organization.
Subject Alternative Name certificates, or SAN certificates, allow an organization to cover multiple domains. For example, TestOut could cover testout.com, testout.net, or even labsim.com with the same certificate.
Wildcard certificates are like SAN certificates. Wildcard certificates allow an organization to cover unlimited subdomains. For example, TestOut could cover any site that ended in testout.com with the same wildcard certificate.
Code-signing certificates are used by app developers to prove that an application is legitimate and hasn't been altered or compromised. When the user installs a program and there's no certificate, they receive a warning that they shouldn't trust the app.

Self-signed certificates are certificates that haven't been validated and signed by a CA. These certificates are easy and free to make, but they don't provide the same protection and security as a CA-validated certificate. If a website uses a self-signed certificate, the user sees a warning when visiting the site.
Secure, encrypted emails are generally sent using the S/MIME Protocol. When you send secure emails, you need to know the recipient's public key, which you find in email certificates. These certificates are usually used within an organization that uses its own CA, but some public CAs also provide email certificates.
You can use certificates to identify and validate individual users and computers. You generally see these kinds of certificates in a network environment where they're used to validate a computer or user to the server.
The most common use for certificates is for websites that use SSL or TLS. These certificates validate that the website is authentic and secure so that users feel safe.
When a site wants to purchase a certificate, there are three different validation levels a CA can offer. These are domain validation, organization validation, and extended validation.
Domain validation is the lowest level and isn't very secure. A CA issues a domain-validated certificate to anyone who's listed as the domain administrator in the WHOIS record. The CA usually validates this with a simple phone call or email, which isn't hard to spoof. These certificates can be issued usually within a matter of minutes.
An organization validation requires the certificate purchaser to not only prove that they're a domain administrator, but also that the organization is real. This process varies with each CA, but it's more in-depth than a domain validation. These certificates may take 1 to 3 days to be issued.
Extended validation is the highest level of trust. An extended validation requires the purchaser to prove that they're the domain administrator and also requires a much more thorough vetting of the organization itself. These certificates may take 1 to 5 days to be issued.
That's it for this lesson. In this lesson, we discussed the different types of PKI certificates and how CAs implement them. We also looked at the three validation levels for SSL certificates and how each level differs.

3.5.4 Certificate Types Facts

PKI certificates are used to verify an organization’s identity and ownership of a public key. When an organization requests a certificate, they must choose which type they need. The Certificate Authority needs to validate the organization before issuing the certificate. The level of validation depends on the certificate type being requested.

This lesson covers the following topics:

- Certificate types
- Certificate signing requests

Certificate Types

Depending on the use and situation, there are different types of public key infrastructure (PKI) certificates. The following table explains what these certificate types are and how they can be used:

Certificate Type	Description
Root certificate	A root certificate is the first certificate that a Certificate Authority creates. Root certificates are: • Self-signed certificates. These certificates go through a different validation process, which varies depending on the certificate and organization. • Used to sign lower-level certificates such as intermediate certificates.
Subject Alternative Name (SAN) certificate	SAN certificates allow an organization to cover multiple domains with one certificate. For example, TestOut could cover the following domains in a single SAN certificate:

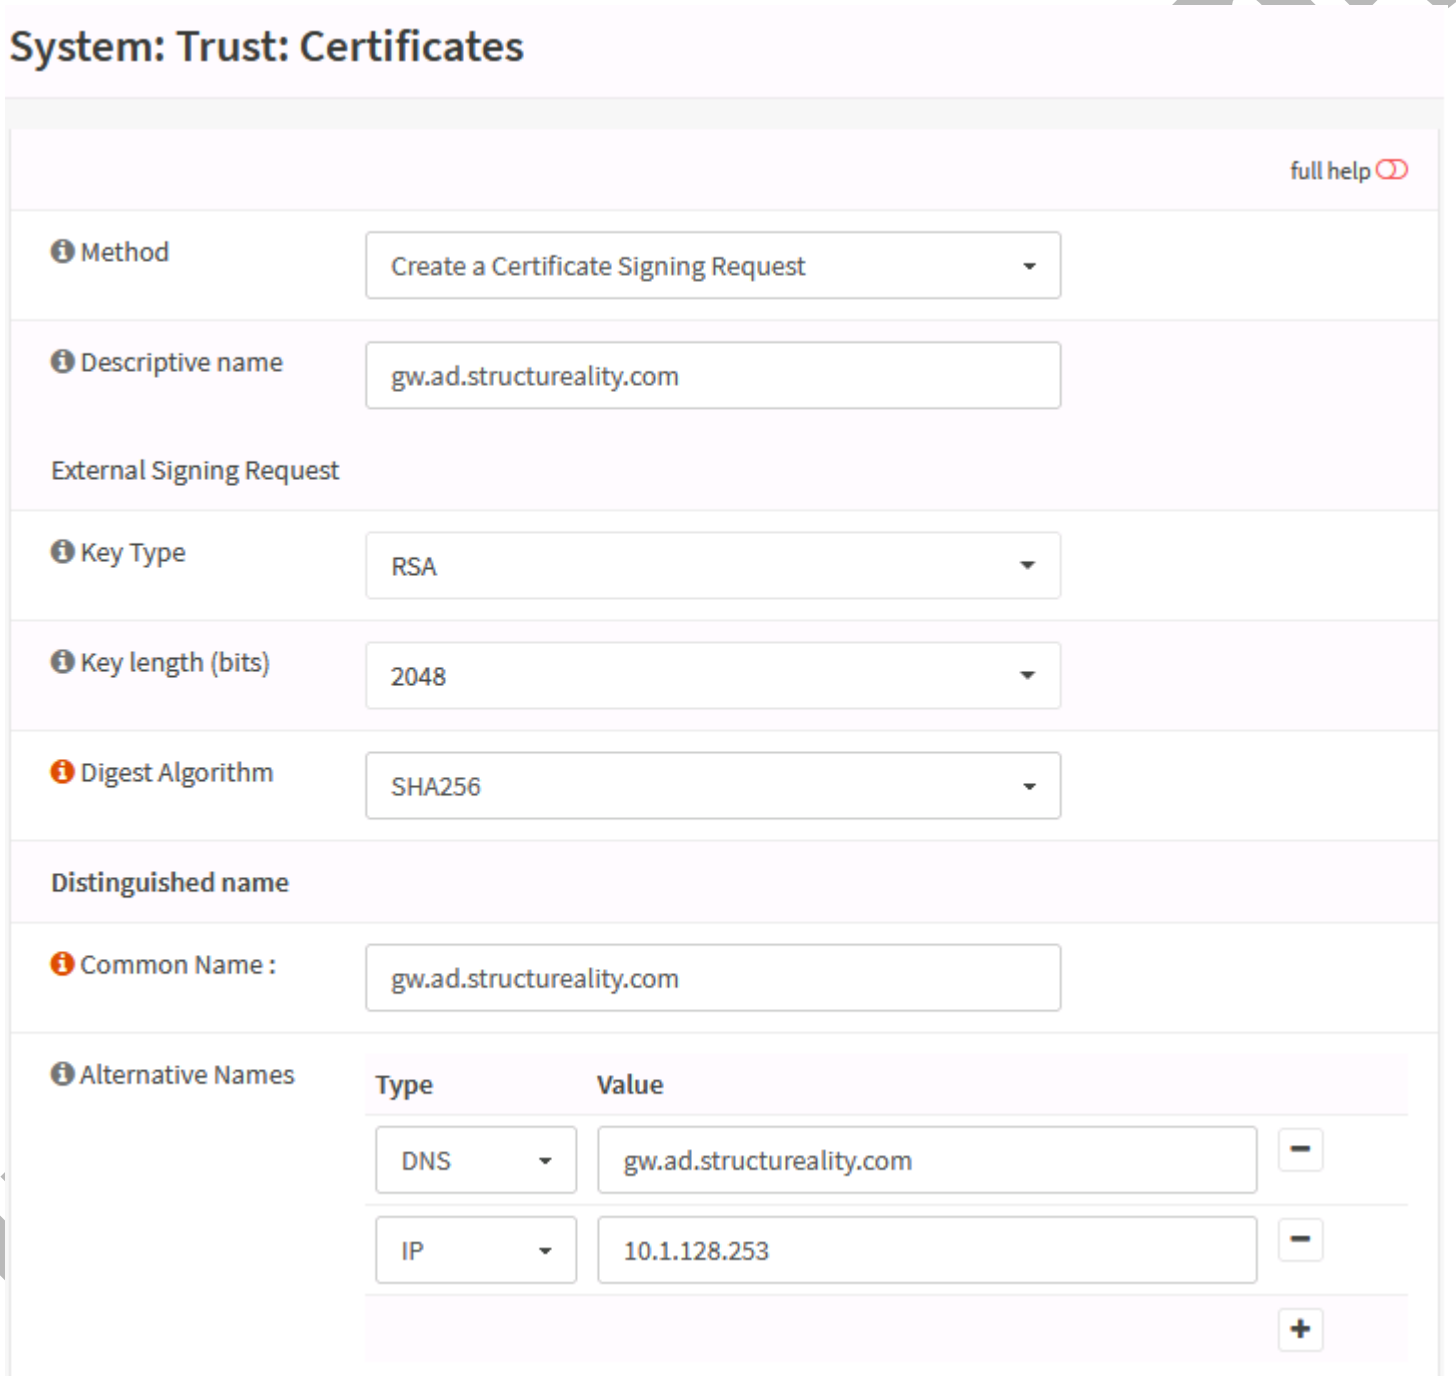
Certificate Type	Description
	• TestOut.com • TestOut.net • LabSim.com
Wildcard certificate	Wildcard certificates are similar to SAN certificates. But instead of covering multiple domains, the organization can cover one domain and multiple subdomains. For example, TestOut could cover the following in one certificate: • quiz.testout.com • labs.testout.com • videos.testout.com
Code-signing certificate	Code-signing certificates are used by app developers to prove their application is legitimate. If a user tries to run an app that does not have a certificate, they will receive an error stating that the app cannot be trusted. The user can decide to close the app or run it.
Self-signed certificate	Self-signed certificates are certificates that have not been validated or signed by a CA. • Self-signed certificates are easy and free to make. • Self-signed certificates do not provide the same protection and security as a CA-validated certificate. • When a user visits a website using a self-signed certificate, they see a warning that the certificate is not trusted.
Email certificate	Secure, encrypted emails are sent using the S/MIME Protocol. • Senders need to know the recipient's public key when sending a secure email. The public key is found in email certificates. • Email certificates are mainly used in an organization that uses its own CA. However, some public CAs provide email certificates as well.
User and computer certificate	User and computer certificates are used in a network environment to identify and validate specific users or computers. When a user or computer logs into a network, their certificate is sent to the server for validation. This provides extra security to the network.

Certificate Signing Requests

Registration is the process by which end users create an account with the CA and become authorized to request certificates. The exact processes by which users are authorized and their identity proven are determined by the CA implementation. For example, in a Windows domain network, users and devices can often auto-enroll with the CA just by authenticating to Active Directory. A third-party CA might perform a range of tests to ensure that a subject is who they claim to be. It is in the CA's interest to ensure that it only issues certificates to legitimate users, or its reputation will suffer.

When a subject wants to obtain a certificate, it first generates a key pair comprising private and public asymmetric keys for the chosen cipher, such as RSA or ECC, and key length. The private key must be kept well protected and known only to the subject. The subject then completes a certificate signing request (CSR) and submits it to the CA. The CSR is a file containing the information the subject wants to use in the certificate, including its public key.

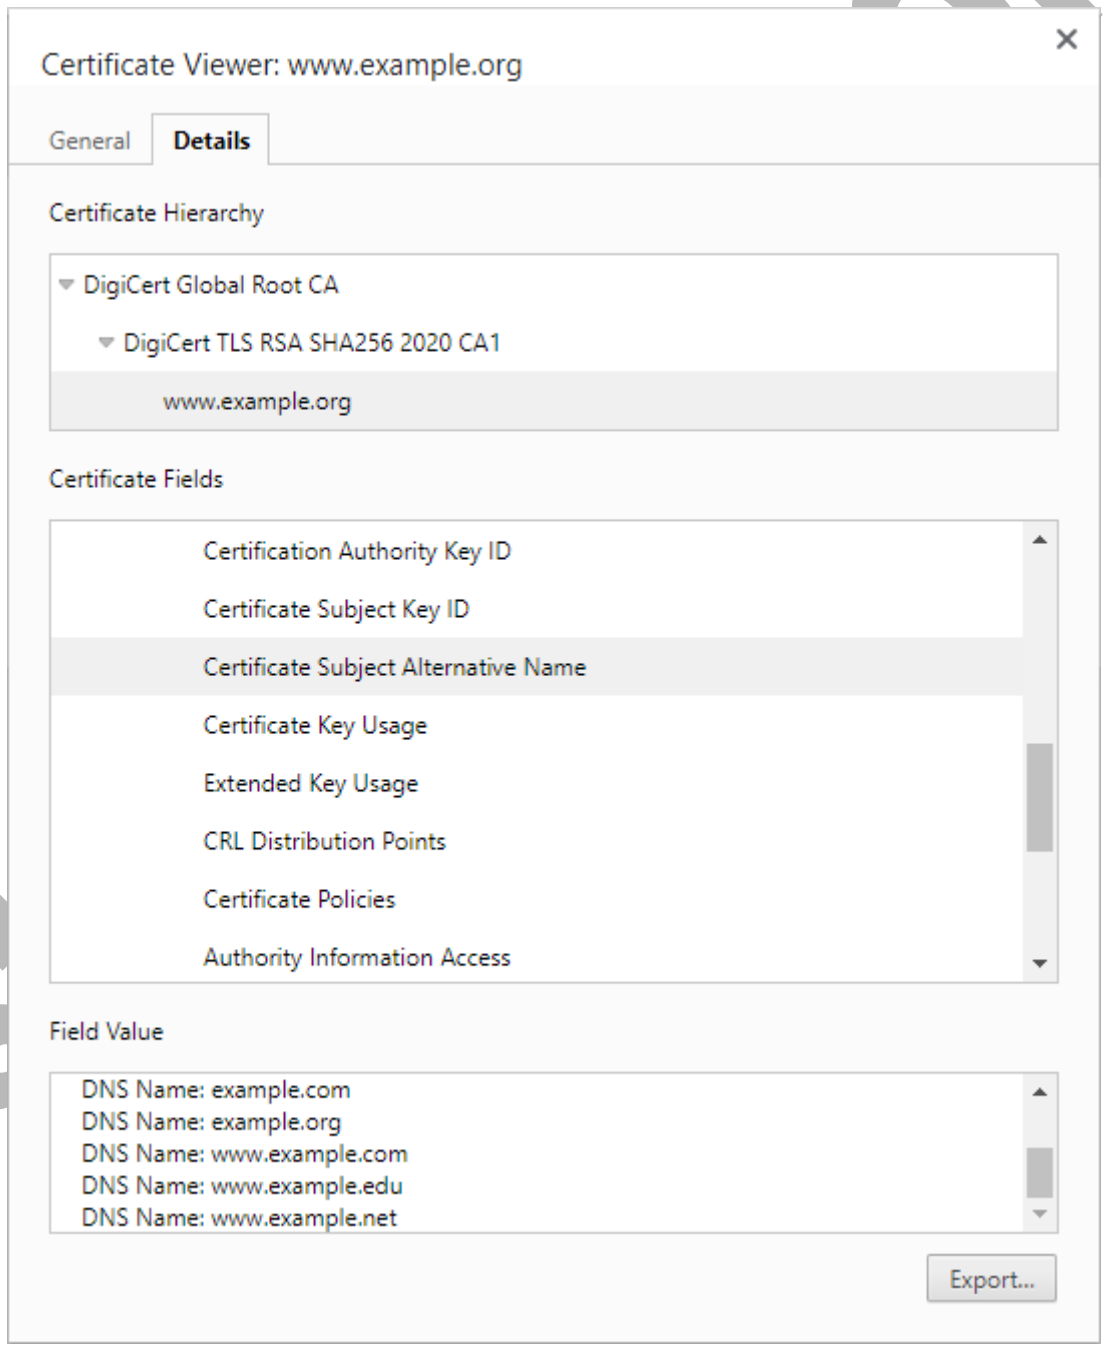
The CA reviews the certificate and checks that the information is valid. For a web server, this may simply mean verifying that the subject name and fully qualified domain name (FQDN) are identical and verifying that the CSR was initiated by the person administratively responsible for the domain, as identified in the domain's WHOIS records. If the request is accepted, the CA signs the certificate and sends it to the subject.



Using a web form in the OPNsense firewall appliance to request a certificate. The DNS and IP alternative names must match the values that clients will use to browse the site.

When certificates were first introduced, the common name (CN) attribute was used to identify the fully qualified domain name (FQDN) by which the server is accessed, such as www.comptia.org . This usage grew by custom rather than design, however. The CN attribute can contain different kinds of information, making it difficult for a browser to interpret it correctly. Consequently, the CN attribute is now deprecated as a method of validating a subject identity that needs to resolve to some type of network address.

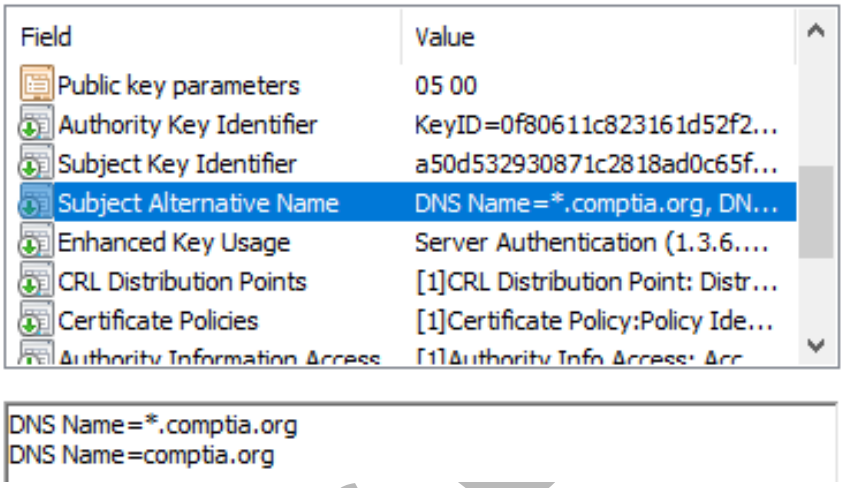
The subject alternative name (SAN) extension field is structured to represent different types of identifiers, including FQDNs and IP addresses. If a certificate is configured with a SAN, the browser should validate that and ignore the CN value.



The example domain's certificate is configured with alternative subject names for different top-level domains and subdomains. (Screenshot used with permission from Microsoft.)

It is still safer to put the FQDN in the CN because not all browsers and implementations stay up to date with the standards.

The SAN field also allows a certificate to represent different subdomains, such as www.comptia.org and members.comptia.org . Listing the specific subdomains is more secure, but if a new subdomain is added, a new certificate must be issued. A **wildcard** domain, such as *.comptia.org , means that the certificate issued to the parent domain will be accepted as valid for all subdomains (to a single level).



CompTIA's website certificate configured with a wildcard domain, allowing access via either https://comptia.org or https://www.comptia.org. (Screenshot used with permission from Microsoft.)

A certificate also contains fields for Organization (O), Organizational Unit (OU), Locality (L), State (ST), and Country (C). These are concatenated with the common name to form a Distinguished Name (DN). For example, Example LLC's DN could be: CN=www.example.com, OU=Web Hosting, O=Example LLC, L=Chicago, ST=Illinois, C=US .

Different certificate types can be used for purposes other than server/computer identification. User accounts can be issued with email certificates, in which case the SAN is an RFC 822 email address. A code-signing certificate is used to verify the publisher or developer of software and scripts. These do not use a SAN, but the CA must validate the organization and locale details to ensure accuracy and that a rogue developer is not attempting to impersonate a well-known software company.

3.5.5 Manage Certificates (Demo Video)

Transcript:

In this demonstration, we're going to practice managing the public key infrastructure.

To do this, we'll use the Windows Server 2022 system that already has Active Directory Certificate Services installed, which makes it a certificate authority, or CA.
It's called Active Directory Certificate Services because the CA itself is integrated with Active Directory to authenticate certificate requests.
We're going to practice requesting, approving, issuing, and revoking certificates on the CA. In order to manage the CA, we need to launch the CA console by clicking Tools and Certificate Authority.
We can see here the CA itself and the certificate categories: Revoke Certificates, Issue Certificates, Pending Requests, and Failed Requests.
By default, the CA is set to automatically approve any new certificate requests. However, we don't want that to happen.

Instead, we want to move the certificate request to a pending state, here in Pending Requests, until an administrator comes through and manually reviews the request. Then he or she either approves or denies it.
To make sure that this is set correctly, we're going to right-click on the CA, go to Properties, go to Policy Module, go to Properties again. We'll change this so that new certificate requests are sent to Pending until approved.
Now we are given a prompt that we need to restart certificate services for that change to go into effect. I'll do that now by right clicking on the CA, going to All Tasks, then Stop Service. Then I'll do the same thing and Start the service again.
With that setting checked, we want to request a new certificate now. There are two different ways to do this.
With the first method, I install the certificate authority and I also install the Certificate Enrollment Page. This allows users to request certificates using a web page running from the Internet Information Server Service on the CA itself.
Let's go ahead and open up Microsoft Edge. We're going to point it to the right URL for the local host. There it is. It's going to be local host /certsrv. You see here the first task on the list is request a certificate.
Alright, we're going to come back to this window a little bit later. The second method is using the MMC console. Let's go ahead and right-click on the window. Go to Run, MMC, and hit Yes.
First, we're going to need to add some snap-ins. So, we're going to go Add or Remove Snap-in. We need the Certificate snap-in. Go to Add, My User Account, Finish, and Okay. The snap-in is here.
Now we can see all the different types of certificates that we can create for our current user. We're going to actually create one under Personal.
Go to Certificates, right-click, click All Tasks, and Request New Certificate. Go through Next, Next, Select User, Enroll, and Finish.
Now let's go back to our CA console. If we go into Pending Requests, we can see that it was properly sent straight to our Pending Requests. It wasn't actually issued.
From this screen, we can view the pending request and see the request ID here.
This is where we can now request whether we want to approve or deny this certificate. If we right-click it, we have the option to issue or deny. Let's go ahead and issue this certificate.
Now the certificate request is gone from Pending. If we go to Issued Certificates, we can now see It's been officially issued.
We can see all sorts of information here. For example, who it's issued to, who it was issued by, and the certificate authority, which is our certificate authority.
We see the certification expiration date here and its intended purpose. So, that's a personal certificate. It's intended for EFS encryptions, securing email, and client authentication. It was created using the user certificate template.
If we double-click the certificate, we can view the date range when it's valid and we can go to the Details tab. Here we can view additional details about the certificate. And if we click the Certificate Path tab, we can view the certificate path up to the root CA.
In this demonstration, we only have one CA and there are no subordinate CAs. So, the certificate path is actually really short. But in many organizations, you'll have one or more root CAs with subordinate CAs associated with it.
So, the Certificate Path tab can be used to view the path through the subordinate CAs up to the root CA. Let's close this and go back to our CA console.
There may be different situations when the certificate shouldn't be used. For example, this is the case if the private key gets compromised in some way. In these situations, we should no longer use this certificate for encryption.
We would need to revoke it. To do this, we simply right-click the certificate, go to All Tasks, and to Revoke. You can specify a reason code for why this certificate is being revoked.
If you look, the last code is Certificate Hold. This is used in situations where you think there might be a problem with the certificate but you're not 100 percent sure.
We want to put the certificate on hold without fully revoking it so that we can verify whether or not it's an issue that would require it to be fully revoked or not. If there is no issue, we can take it off hold and continue using it. If there's a problem, we can fully revoke it.
If you were to use one of the other options here to revoke the certificate, such as Key Compromise, you couldn't unrevoke it. It's gone. You'll have to issue a new certificate. Let's go ahead and put it in Certificate Hold and hit Yes.
You see it clears out the Issued Certificates, and now it's on hold. Let's go to Revoke. You can see right here the revocation reason: Certificate Hold.
Because we just held it instead of revoking it all the way, we can unrevoke it. To do this, we right-click, go to All Tasks, and Unrevoke Certificate. Alright, it removed it.
If we go back to Issued Certificates, we can see the certificate is back for use again. Let's go ahead and do this again. But this time, go to All Tasks and revoke it for a different reason.
Let's go ahead and just say Key Compromise. Hit Yes. Alright, now it's revoked. If we go back to Revoked Certificates and we right-click, go to All Tasks, and try to unrevoke it, we can't.

We get this error: unrevoke command failed. Certificates can only be unrevoked if they're revoked with reason code Certificate Hold.
So, this certificate no longer can be used. You would have to reissue a new certificate in order for them to use it.
After you've revoked a certificate, you need to let everyone know that the certificate has been revoked and shouldn't be used anymore. This is done by publishing the latest Certificate Revocation List.
To do this, we go to our Revoked Certificates folder, we right-click, go to All Tasks, and then click Publish. This will publish the latest list of revoked certificates to the Certificate Revocation List.
There are two different types of Certificate Revocation Lists, or CRLs. You can publish a full CRL, which contains a list of all the revoked certificates. Or we can just publish a delta CRL which only contains the certificates that have been revoked since the last time the full CRL was published.
For our purposes, we're going to publish a new CRL because it's the first time we've actually published a CRL from this CA. Let's go ahead and click Okay.
If you forget to do this manually, it's okay because the CA should be configured to automatically publish the CRL at a particular interval. If we right-click, hit Revoke Certificates again, and go to Properties this time, we can see the CRL publishing parameters.
By default, the full CRL is published once a week and the delta CRLs are published once a day.
If we click the View CRLs tab, then click CRL, and then click the revocation list, we can see the current CRL and the certificates that were just revoked. Because this CA hasn't been in use very long, there are not many certificates to be revoked. Let's go ahead and close it. Click OK and OK.
Alright, now let's look at the properties of the CA. Let's right-click the Root CA and Properties. Alright, we're going to go to the Extensions tab. The Extensions tab has two acronyms that are very important to understand.
The first one is Authority Information Access, or AIA. The AIA allows end users to obtain the certificate used by the CA itself. This can be very useful if you have a root CA that is offline for security reasons.
This is not an uncommon configuration. Some organizations will keep their root CAs offline all the time to make them less susceptible to compromise. But we still need to have a copy of the root CA certificate.
To make this possible, we use AIA to publish a copy of the root CA certificate to some other location so that users can still access the root CA certificate. This is important because we need that root CA certificate with the CA's public key in order to verify digital signatures that the CA has implemented.
If the CA digitally signs something, you must have a copy of its public key to verify that signature. AIA makes that public key available offline. If we didn't do this and the root CA was offline, we'd have to figure out some other way to get a copy of that key.
In addition to AIA, we also have CRL and CRL Distribution Point, also known as CDP. This is where users go to get a copy of the latest CRL. The same issue exists here as exists with the root CA's public key.
If the root CA is offline, we can't access the CRL. We can't let everybody know which certificates have been revoked. What we can do is publish the CRL to some other location that clients can access.
For example, we can publish it to Active Directory via LDAP. We could access it on a web page, or we could put it in the file system.
Let's go ahead and click Cancel. If we go back to our CertSRV web page, we can see there's an option to download the CA certificate or view the certificate chain or CRL.
This option, Download a CA certificate, is AIA. This one is CDP. If we click this option, we could download the latest CRL or the latest delta CRL.
In this demonstration, we covered various aspects of managing certificates within the public key infrastructure. We discussed requesting certificates, manual approval, issuing certificates, and revoking certificates.
We also delved into the availability of the CA's public keys via AIA and the publication of the Certificate Revocation List (CRL) to inform users about revoked certificates.

3.5.6 Manage Certificates (Simulation)

Scenario

You are the IT administrator for a growing corporate network. You manage the certification authority for your network. As part of your daily routine, you perform several certificate management tasks. CorpCA, the certification authority, is a guest server on CorpServer2.

In this lab, your task is to complete the following:

- Your network uses smart cards to control access to sensitive computers. Currently, the approval process dictates that you manually approve smart card certificate requests.
  Approve pending certificate requests for smart card certificates from tsutton and mmallory.
- Deny the pending web server certificate request for CorpSrv12.
- User bchan lost his smartcard. Revoke the certificate assigned to bchan.CorpNet.com using the **Key Compromise** reason code.
- Unrevoke the CorpDev3 certificate.

Explanation

Complete this lab as follows:

1. Access Certification Authority on the CORPSERVER2 server.
   a. From Hyper-V Manager, select **CORPSERVER2** .
   b. Maximize the window for better viewing.
   c. From the Virtual Machines pane, double-click **CorpCA** .
   d. From the Server Manager's menu bar, select **Tools > Certification Authority** .
   e. Maximize the window for better viewing.
   f. From the left pane, expand **CorpCA-CA** .
2. Approve the pending certificate request for tsutton and mmallory.
   a. Select **Pending Requests** .
   b. From the right pane, scroll until you can see the **Requester Name** column.
   c. Right-click on the row that contains **tsutton** and select **All Tasks > Issue** to approve the certificate.
   d. Right-click on the row that contains **mmallory** and select **All Tasks > Issue** .
3. Deny the pending request for CorpSrv12.
   a. Right-click on the row that contains **CorpSrv12.CorpNet.com** and select **All Tasks** > **Deny** .
   b. Select **Yes** to confirm the denial.
4. Revoke bchan's certificates.
   a. From the left pane, select **Issued Certificates** .
   b. From the right pane, right-click **bchan.CorpNet.com** and select **All Tasks** > **Revoke Certificate** .
   c. Using the *Reason code* drop-down menu list, select **Key Compromise** .
   d. Select **Yes** .
5. Unrevoke the CorpDev3 certificate.
   a. From the left pane, select **Revoked Certificates** .
   b. From the right pane, right-click **CorpDev3.CorpNet.com** and select **All Tasks** > **Unrevoke Certificate** .

3.5.7 Certificate Concepts (Lesson Video)

Transcript:

Using digital certificates to share public keys and validate organizations has become a key component to doing business over the internet. Certificate Authorities, or CAs, are trusted organizations that validate and administer these certificates. In this lesson, I'll go over how CAs are set up and managed.

To fully understand how certificates work, you need to understand how CAs are set up. To increase security, CAs operate in a hierarchy of multiple CAs. This is done so that if one of the CAs is compromised, only the certificates it issued need to be revalidated.
The first CA is the Root CA. This is a self-signed certificate and is used to validate additional CAs.
Under the Root CA, you have Subordinate CAs, also known as Intermediate CAs. You can have multiple Intermediate CAs based on their policies and regulations. The Intermediate CAs validate the Issuing Certificate Authorities and the

Issuing CA is the one that hands out certificates. When you check the certification path in a web browser, you can usually see this structure.
For example, when we look at TestOut's certificate, we see that their server certificate was issued by this Intermediate CA, which was signed by this Root CA. This structure is known as certificate chaining, or the chain of trust.
Certificate chaining is done to protect the root certificate. If the root certificate is ever compromised, all certificates that have been issued underneath it are now invalid and need to be redone.
Another common method of protecting the Root CA is to keep it offline and only bring it online when it needs to authorize a new Intermediate CA.
Once the Root CA has been set up and the intermediate certificates issued, the Root CA is generally taken offline. This means that it's isolated from network access and is usually completely turned off. If an Intermediate CA is compromised, only the certificates they issued need to be reissued. In other words, not every certificate that was issued under the Root CA is compromised.
The problem with this is that the Root CA can't manage and update the Certificate Revocation List, or CRL, if it's offline. To remedy this, the Intermediate CAs can be set up to manage the CRL, or a specific Intermediate CA can be configured to handle this job.
Instead of having browsers constantly checking the CRLs, the Online Certificate Status Protocol, or OCSP, was created to replace CRLs and can be used to determine the validity of certificates. Let's see how this works.
When OCSP servers, also called responders, receive a request from the web browser, they check with the CA and send an up-to-date certificate status. This frees up CAs from having to maintain their own CRLs.
To further help with performance, a network might use OCSP stapling. Stapling simply means that the server that holds the certificate also provides any revocation information.
This works by having the certificate holder send a query to the OCSP responder at set intervals. Then the server staples that timestamped response to its certificate so that in the first SSL or TSL handshake the OCSP validation is already attached. Now, the user's browser doesn't need to perform a separate OCSP request.
Keep in mind that it's possible for a man-in-the-middle attack to intercept certificates during the handshake. This would allow a hacker to set up a malicious site using a valid certificate. This can be prevented using certificate pinning.
Certificate pinning is when an application, such as a web browser, has the server's certificate hard coded in the browser itself. When the application connects to the server, it downloads and checks the certificates. If they don't match, the application blocks the connection. Just know that certificate pinning was never really adopted by modern browsers, so it would mostly be used inside of an organization that's running their own CA.
Let's shift gears to trust models. All CAs start with a single trust model. This means that there's one Root CA for the organization that issues and manages certificates. As you've already seen, a hierarchical structure is mainly used. It starts with the root certificate and multiple Intermediate CAs below it.
It's also possible for you to set up a mesh model. In a mesh model, multiple CAs issue certificates to each other. This works great because if one CA is compromised, those certificates can still be valid because other CAs have authenticated them. The problem with this model is that it becomes extremely difficult to scale up with growth.
Another thing to consider is how trusts can be set up when one organization who has their own CA structure wants to partner with another organization that has their own CA structure. In this scenario, there needs to be a way for each organization to trust the certificates issued by the other's CAs. This can be done by setting up a bridge model in which both hierarchies trust each other. In this case, clients in both organizations trust certificates issued by CAs of either organization. You can also be more restrictive by setting up trusts with individual CAs that are lower on the hierarchy.
Another common setup is the web of trust. Instead of using a CA, everyone is a trusted authority.
For example, if Craig trusts Ethan and Lynette trusts Craig, Lynette will also have an indirect trust with Ethan. In other words, you trust a friend of a friend. We see this setup often in PGP.
Implementing the proper model can help ensure that certificates are properly maintained and validated. Of course, all of this also relies on keeping our encryption keys safe.
Keeping a backup of private keys is important, but you'll need to make sure that they can't be accessed unless absolutely necessary. Normally, the CA never gets the user's private keys.
You can, though, use key archival to back up private keys. All this means is that the user sends their private key in a secure transmission to the CA to keep safe. The problem with this is that a serious security breach can occur if private keys are compromised. The advantage is that the archive of private keys is readily available if any are lost or corrupted.
Key escrow is like key archival, except that keys are sent to a trusted third party instead of the CA holding the keys. This is often done for security or legal purposes. Getting access to these keys may require legal action, and this is by design. For example, if law enforcement needs to access and analyze emails, they would need a court order to get the keys needed.
That's it for this lesson. In this lesson, we discussed how CAs are set up to manage certificates. We first looked at the concept of certificate chaining, which is the method of using a hierarchical certificate structure. Then we covered the

difference in online and offline CAs and the best practice of leaving them offline whenever possible. Finally, we discussed different trust models and how to assure key safety through key archival or escrow services.

3.5.8 Certificate Concepts Facts

Using digital certificates to share public keys and validate organizations is a critical component of doing business over the internet. Certificate authorities (CAs) are the trusted organizations that validate and administer digital certificates.

This lesson covers the following topics:

- Certificate revocation
- Root of Trust
- Single CA
- Third-party CAs
- Private key safety

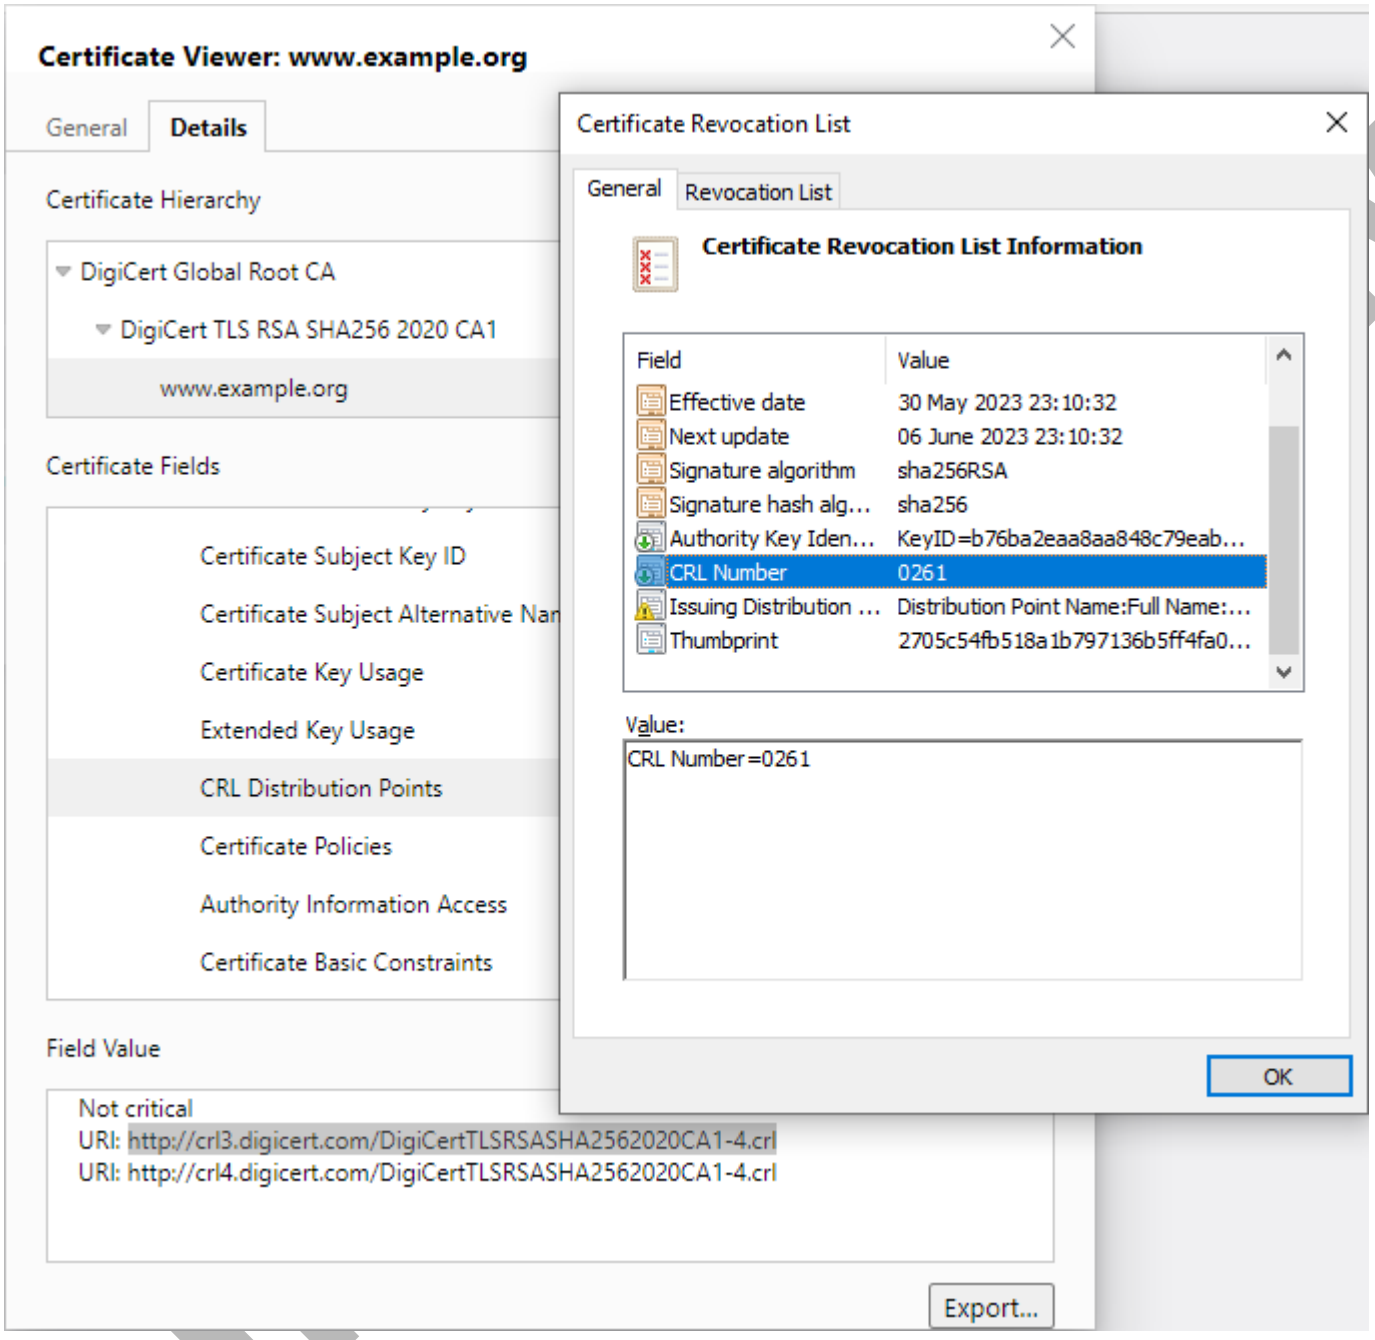
Certificate Revocation

A certificate may be revoked or suspended:

- A revoked certificate is no longer valid and cannot be "un-revoked" or reinstated.
- A suspended certificate can be re-enabled.

A certificate may be revoked or suspended by the owner or the CA for many reasons. For example, the private key may have been compromised, or the business could have closed, a user could have left the company, a domain name could have been changed, the certificate could have been misused, and so on. These reasons are codified under choices such as Unspecified, Key Compromise, CA Compromise, Superseded, or Cessation of Operation. A suspended key is given the code Certificate Hold.

There must be a mechanism to inform users whether a certificate is valid, revoked, or suspended. A CA must maintain a **certificate revocation list (CRL)** of all revoked and suspended certificates. The CRL must be accessible to anyone relying on the validity of the CA's certificates. Each certificate should contain information for the browser on how to check the CRL.



The distribution point field in a digital certificate identifies the location of the list of revoked certificates, which are published in a CRL file signed by the CA. (Screenshot used with permission from Microsoft.)

A CRL has the following attributes:

- **Publish Period** - the date and time on which the CRL is published. Most CAs are set up to publish the CRL automatically.
- **Distribution Point(s)** - the location(s) to which the CRL is published.
- **Validity Period** - the period during which the CRL is considered authoritative. This is usually a bit longer than the publish period (for example, if the publish period was every 24 hours, the validity period might be 25 hours).

- **Signature** - the CRL is signed by the CA to verify its authenticity.

With the CRL system, there is a risk that the certificate might be revoked but still accepted by clients because an up-to-date CRL has not been published. A further problem is that the browser (or other application) may not be configured to perform CRL checking, although this now tends to be the case only with legacy browser software.

Another means of providing up-to-date information is to check the certificate's status on an Online Certificate Status Protocol (OCSP) server. Rather than return a whole CRL, this communicates the requested certificate's status. Details of the OCSP responder service should be published in the certificate.

Most OCSP servers can query the certificate database directly and obtain the real-time status of a certificate. Other OCSP servers depend on the CRLs and are limited by the CRL publishing interval.

Root of Trust

The *root of trust model* defines how users and different CAs can trust one another. Each CA issues itself a certificate. This is referred to as the root certificate . The root certificate is self-signed, meaning the CA server signs a certificate issued to itself. A root certificate uses an RSA key size of 2,048 or 4,096 bits or the ECC equivalent. The subject of the root certificate is set to the organization/CA name, such as "CompTIA Root CA."

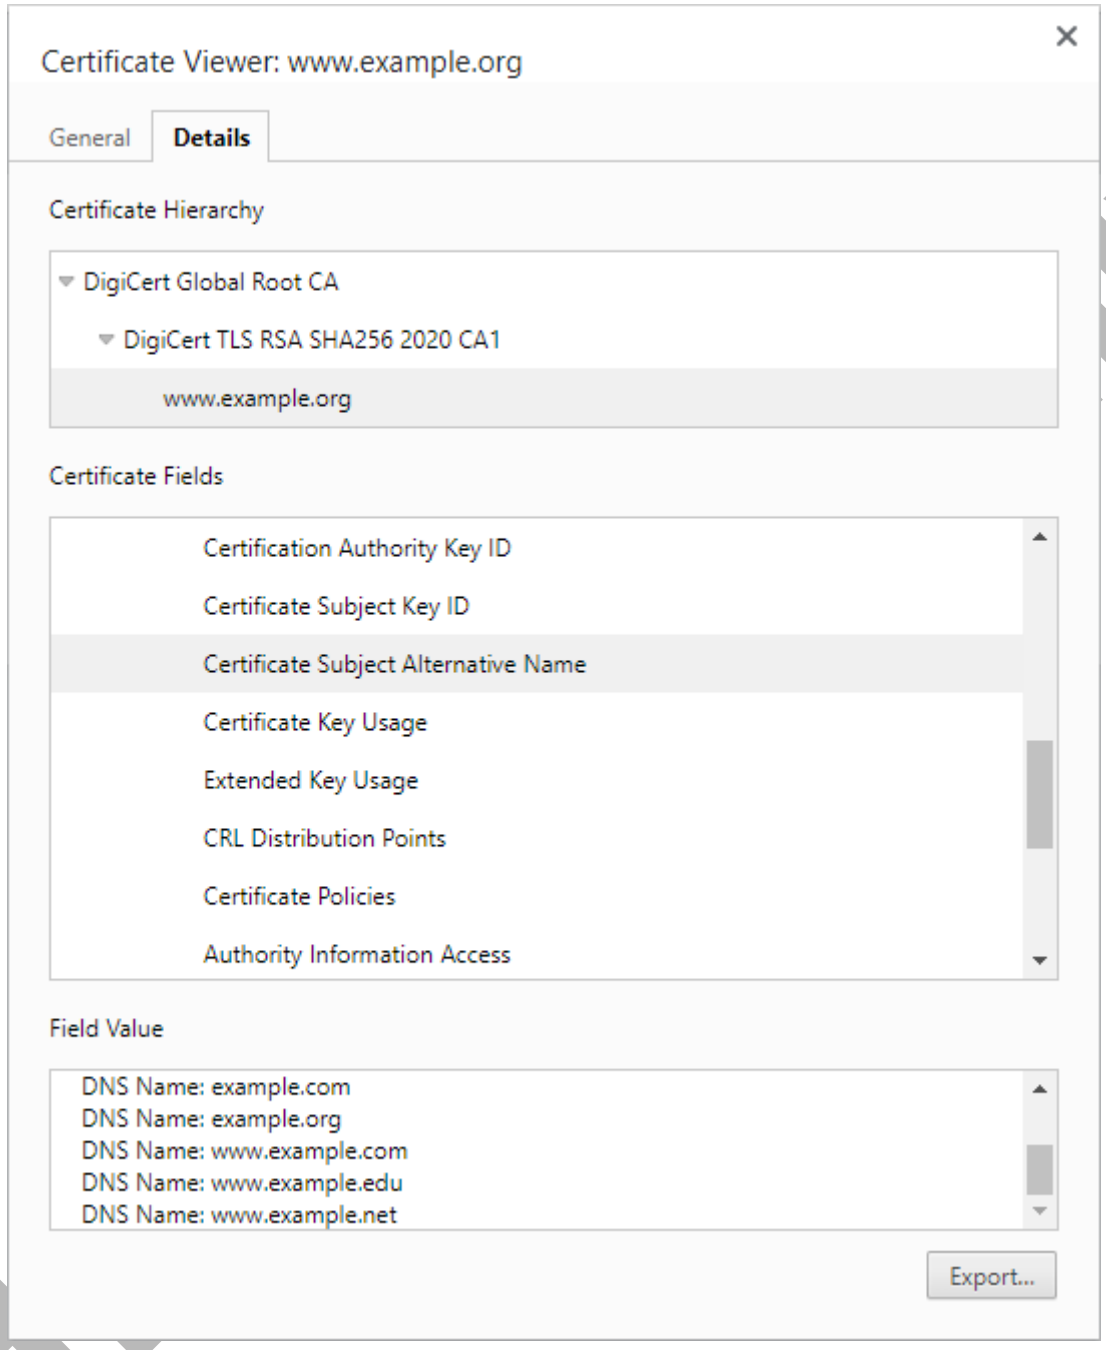
The root certificate can be used to sign other certificates issued by the CA. Installing the CA's root certificate means that hosts will automatically trust any certificates signed by that CA.

Single CA

In this simple model, a single root CA issues certificates directly to users and computers. This single CA model is often used on private networks. The problem with this approach is that the single CA server is very exposed. If it is compromised, the whole PKI collapses.

Third-party CAs

Most third-party CAs operate a hierarchical model. In the hierarchical model, the root CA issues certificates to one or more intermediate CAs. The intermediate CAs issue certificates to subjects (leaf or end entities). This model has the advantage that different intermediate CAs can be set up with certificate policies, enabling users to perceive clearly what a particular certificate is designed for. Each leaf certificate can be traced to the root CA along the certification path. This is also referred to as certificate chaining or a *chain of trust* .



The web server for www.example.org is identified by a certificate issued by the DigiCert TLS CA1 intermediate CA. The intermediate CA's certificate is signed by DigiCert's Global Root CA (Screenshot used with permission from Microsoft).

In some circumstances, using PKI can be too difficult or expensive to manage. Any machine, web server, or program code can be deployed with a self-signed certificate . For example, the web administrative interfaces of consumer routers are often only protected by a self-signed certificate. Self-signed certificates can also be useful in development and test environments. The operating system or browser will mark self-signed certificates as untrusted, but a user can choose to override this. The nature of self-signed certificates makes them very difficult to validate. They should not be used to protect critical hosts and applications.

Private Key Safety

To ensure data can always be recovered, you should create a backup of the private keys. It is important to have a backup and, equally important, that the backup is kept safe. The following table shows two main methods to backup private keys:

Key Backup Method	Description
Key archival	In key archival, the key is backed up by the CA. To do this, the user sends the private key in a secure transmission to the CA to back it up. This method is often used in an organization that manages its own CA. If keys are lost, they will be readily available and easily accessed. However, if the CA is breached, all private keys will be compromised.
Key escrow	If a private or secret key is lost or damaged, ciphertexts cannot be recovered unless a backup of the key has been made. Making copies of the key is problematic as it becomes more likely that a copy will be compromised and more difficult to detect that a compromise has occurred. These issues can be mitigated by using escrow and M of N controls. Escrow means that something is held independently. In terms of key management, this refers to archiving a key (or keys) with a third party. M of N means that an operation cannot be performed by a single individual. Instead, a quorum (M) of available persons (N) must agree to authorize the operation. A key can be split into one or more parts. Each part can be held by separate escrow providers, reducing the risk of compromise. An account with permission to access a key held in escrow is referred to as a key recovery agent (KRA). A recovery policy can require two or more KRAs to authorize the operation. This mitigates the risk of a KRA attempting to impersonate the key owner.

3.5.9 Certificates and Certificate Authorities

3.5.10 Practice Questions (Section Quiz)

q_cryt_pki_ca_01_secp8

Which aspect of a certificate makes it a reliable and useful mechanism for proving the identity of a person, system, or service on the internet?

Answers:

- ***It is a trusted third party.**
- It uses electronic signatures.
- It provides ease of use.
- It is a digital mechanism rather than a physical one.

Explanation:

The use of a trusted third party (called a certificate authority or CA) is what makes certificates a reliable and useful mechanism for proving the identity of a person, system, or service on the internet. The CA issues proof of identity to each organization in the form of a certificate. The fact that all entities trust the CA makes the certificates trusted and valuable.

A certificate only proves identity; it does not prove reliability. Electronic signatures are a form of certificate that verifies identity. While electronic signatures prove identity, they do so only because both parties trust the authority of the CA, not because the

signature exists. It is true that certificates are easy to use. However, ease of use does not make them reliable. Certificates are a digital mechanism, which makes them suited for use on the internet. However, that alone does not make them reliable or useful.

q_cryt_pki_ca_02_secp8

An SSL client has determined that the certificate authority (CA) issuing a server's certificate is on its list of trusted CAs.

What is the next step in verifying the server's identity?

Answers:

- The domain on the server certificate must match the CA's domain name.
- The post-master secret must initiate subsequent communication.
- ***The CA's public key validates the CA's digital signature on the server certificate.**
- The master secret is generated from common key code.

Explanation:

Once an SSL client has identified a CA as trusted, it uses the CA's public key to validate the CA's digital signature on the server certificate. If the digital signature can be verified, the client accepts the server certificate as a valid certificate issued by a trusted CA.

SSL clients verify a server's identity using the following steps:

1. The client checks the server's certificate validity period. The authentication process stops if the current date and time fall outside of the validity period.
2. The client verifies that the issuing certificate authority is on its list of trusted CAs.
3. The client uses the CA's public key to validate the CA's digital signature on the server certificate. If the digital signature can be verified, the client accepts the server certificate as a valid certificate issued by a trusted CA.
4. To protect against man-in-the-middle attacks, the client compares the actual DNS name of the server to the DNS name on the certificate.

q_cryt_pki_crl_01_secp8

Certificates can be invalidated by the trusted third party that originally issued the certificate.

What is the name of the mechanism that is used to distribute information about invalid certificates?

Answers:

- ACL
- TACACS
- ***CRL**
- One-way function

Explanation:

The CRL (certificate revocation list) is the mechanism that is used to distribute information about invalid certificates. Each time an application receives a certificate, that application checks the CRL from the certificate authority (CA) that issued the certificate. If the certificate is not on the CRL and its timestamp is still valid, the user is prompted whether or not to accept the certificate.

ACLs are used to protect files and other resources.

TACACS is a remote access centralized authentication system.

One-way functions are common cryptographic mechanisms. None of these technologies are directly used to distribute invalid certificate information.

q_cryt_pki_crl_02_secp8

Which of the following BEST describes the contents of the CRL?

Answers:

- The current status of all certificates issued by a CA
- A list of all expired and revoked certificates
- ***A list of all revoked certificates**
- The archived private keys of all issued certificates

Explanation:

The certificate revocation list (CRL) resides at the CA and consists of a list of certificates that have been previously revoked.

Expired certificates are not put on the CRL; they are automatically invalid because the certificate validity period has passed. Archived private keys are held in key escrow, which is a third party that is trusted to protect the private keys.

q_cryt_pki_crl_03_secp8

Which of the following would require that a certificate be placed on the CRL?

Answers:

- The certificate validity period is exceeded.
- ***The private key is compromised.**
- The signature key size is revealed.
- The encryption key algorithm is revealed.

Explanation:

Certificates are published to the certificate revocation list (CRL) when a condition compromises the integrity of the certificate. If the private key is compromised (discovered), the certificate is no longer proof of identity.

Certificates do not need to be placed on the CRL if their validity period expires. In this case, the certificate simply expires. Knowing the signature key size or the encryption key algorithm does not compromise the integrity of the certificate.

q_cryt_pki_digital_certificates_secp8

You are a security analyst at a large corporation. The company uses digital certificates for secure communication.

One day, you notice that a certificate from a trusted third-party certificate authority (CA) has been flagged as invalid. The certificate is not expired, and the organization it was issued to still exists.

What could be the reason for this, and what should be your next step?

Answers:

- ***The private key associated with the certificate has been compromised. You should immediately inform your supervisor and initiate the process to obtain a new certificate.**
- The certificate was mistakenly flagged as invalid. You should ignore the warning and continue using the certificate.
- The certificate is a fake. You should report the issue to the CA and request a new certificate.
- The certificate was issued by a CA that is no longer trusted. You should replace the certificate with one issued by a trusted CA.

Explanation:

Immediately informing your supervisor and initiating the process to obtain a new certificate is the correct answer. If a certificate is flagged as invalid and the organization it was issued to still exists, it's possible that the private key associated with the certificate has been compromised. In this case, the certificate should be replaced immediately to prevent any potential security breaches.

Ignoring a warning about an invalid certificate could lead to serious security issues, such as data breaches or loss of sensitive information. It's important to investigate and resolve any issues related to digital certificates.

If the certificate was a fake, it would likely not have been accepted by the system in the first place, as it would fail the validation process. However, if this is the case, the issue should be reported to the CA and a new certificate should be requested.

If the CA that issued the certificate is no longer trusted, the certificate would not be flagged as invalid; instead, the system would not accept the certificate at all. If this were the case, the certificate would need to be replaced with one issued by a trusted CA.

q_cryt_pki_ocsp_secp8

Which technology was developed to help improve the efficiency and reliability of checking the validity status of certificates in large, complex environments?

Answers:

- Certificate revocation list
- Key escrow
- Private key recovery
- ***Online Certificate Status Protocol**

Explanation:

Online Certificate Status Protocol (OCSP) is the technology developed to improve the efficiency and reliability of checking the validity status of certificates in large, complex environments. OCSP allows clients to query a CA or registration authority (RA) and quickly learn whether a certificate is valid or has been revoked.

OCSP is a significant improvement over the CRL mechanism. CRLs were static lists that were distributed periodically to CAs and RAs. However, CRLs were often out of date. Key escrow and private key recovery are not related to certificate status checking.

q_cryt_pki_pki_01_secp8

Which of the following is a mechanism for granting and validating certificates?

Answers:

- ***PKI**
- RADIUS
- Kerberos
- AAA

Explanation:

Certificates are obtained from a public key infrastructure (PKI). A PKI is a system that allows a trusted third party to vouch for user identities. A PKI is made up of certificate authorities (CAs), while a CA is an entity trusted to issue, store, and revoke certificates.

Both RADIUS and TACACS+ are protocols used for centralized authentication, authorization, and accounting with remote access. Kerberos is an authentication and authorization program that uses tickets.

q_cryt_pki_pki_02_secp8

A PKI is an implementation for managing which type of encryption?

Answers:

- ***Asymmetric**
- Symmetric
- Hashing
- Steganography

Explanation:

A public key infrastructure (PKI) is a hierarchy of computers that issue and manage certificates. Certificates use asymmetric encryption with a public and private key pair.

Because certificates use asymmetric encryption, and certificates are a key component of PKI, symmetric encryption is not utilized with PKI.

Hashing is the practice of transforming a given key or string of characters into another value for the purpose of security. Hashing is always used for one-way encryption, which makes it a symmetric (not asymmetric) encryption type.

Steganography is a type of encryption where digital content is hidden within another message or physical object to avoid detection. Steganography can be used to hide virtually any type of digital content, including text, image, video, or audio content. This is a type of symmetric encryption that is not part of the PKI process.

q_cryt_pki_purpose_secp8

An organization has tasked a cyber security technician with enhancing its framework after recently experiencing a cyber breach.

What is the value associated with a public key infrastructure (PKI)?

Answers:

- ***It is the framework that establishes trust in using public key cryptography to sign and encrypt messages via digital signatures.**
- It is a cryptoprocessor implemented as a module within the CPU on a computer or mobile device.
- It is a cryptoprocessor that implements hardware through a removable or dedicated form factor, such as plug-in PCIe adaptor cards.
- It summates all revoked and suspended certificates and must be accessible to anyone relying on the validity of the CA's certificates.

Explanation:

In this scenario, a PKI is the preferred framework that helps establish trust in using public key cryptography to sign and encrypt messages via digital signatures.

Not viable in this scenario, a trusted platform module (TPM) is a cryptoprocessor implemented as a module within the CPU on a computer or mobile device.

A hardware security module (HSM) is a cryptoproccessor that implements hardware through a removable or dedicated form factor, such as plug-in peripheral component interconnect express (PCIe) adaptor cards.

A certificate revocation list (CRL) provides a summation of all revoked and suspended certificates and must be accessible to anyone relying on the validity of the certificate authority's (CA's) certificates.

q_cryt_pki_ra_01_secp8

Which of the following is an entity that accepts and validates information contained within a request for a certificate?

Answers:

- ***Registration authority**
- Certificate authority
- Recovery agent
- Enrollment agent

Explanation:

A registration authority (RA) can be used in large enterprise environments to offload client enrollment request processing by handling client verification prior to certificates being issued. The RA accepts registrations, validates identity, and approves or denies certificate requests.

A certificate authority (CA) is an entity trusted to issue, store, and revoke digital certificates. Often, the role of a CA is combined with that of RA. But technically speaking, a CA is the computer that issues the certificate.

Recovery agents are users who are given the ability to restore private keys from the archive.

An enrollment agent is someone who can request a certificate on behalf of another user. Enrollment agents are often used to request certificates used on smart cards.

q_cryt_pki_ra_02_secp8

In the process of obtaining a digital certificate, which entity may a certificate authority rely on to perform the validation of the certificate signing request (CSR)?

Answers:

- Root authority
- ***Registration authority**
- Certificate revocation list
- Online Certificate Status Protocol

Explanation:

Registration authority is the correct answer. Registration authority (RA) is an entity that is certified by a root certificate authority and is authorized to issue certificates for specific uses only. The RA can perform the validation of the certificate signing request (CSR) on behalf of the certificate authority.

A root authority, or root CA, is the top-level certificate authority in a certificate chain. It is responsible for issuing certificates to subordinate CAs, not for validating CSRs.

A Certificate revocation list (CRL) is a list of certificates that have been revoked before their scheduled expiration date and are no longer valid. It does not perform any validation of CSRs.

The Online Certificate Status Protocol (OCSP) is an internet protocol used to obtain the revocation status of a digital certificate. It does not perform any validation of CSRs.

q_cert_types_ca_secp8

In the certificate authority trust model known as a hierarchy, where does trust start?

Answers:

- ***Root CA**
- Issuing CA
- Third-party CA
- Registration authority

Explanation:

Trust starts at the Root CA in all trust models.

An Issuing CA can be a Root CA or a CA at any level below the root.

A third-party CA may be the source of trust, but even then, the trust starts at a Root CA located somewhere.

A registration authority (RA) is a limited-functionality CA where certificates are verified, but no new certificates can be issued.

q_cert_types_code_cert_secp8

Sarah is a software developer for a tech startup, TechInnovate. She has developed a new application that the company plans to distribute to its customers.

Sarah wants to ensure that the application is seen as legitimate and trustworthy by the users and their systems. She also wants to protect the integrity of the application code from being tampered with.

Which type of certificate should Sarah use?

Answers:

- Root certificate
- Subject Alternative Name (SAN) certificate
- ***Code signing certificate**
- Self-signed certificate

Explanation:

A code signing certificate is used by software developers to digitally sign their applications. This proves the legitimacy of the application and ensures that the code has not been tampered with since it was signed. This is exactly what Sarah needs for her application.

A root certificate is the top-most certificate in a certificate chain, used by certificate authorities (CAs) to sign other certificates. It doesn't serve the purpose of validating software applications or protecting their integrity.

A Subject Alternative Name (SAN) certificate is used to secure multiple domains with a single certificate. It doesn't provide the functionality to validate software applications or protect their integrity.

A self-signed certificate is not issued by a trusted CA and would likely cause trust issues with systems and users. It also doesn't provide the functionality to validate software applications or protect their integrity.

q_cert_types_csr_01_secp8

You are a security analyst at a large organization. Your organization uses a third-party certificate authority (CA) for its public key infrastructure (PKI).

One day, you receive a certificate signing request (CSR) from a new department in your organization. The CSR contains a public key and the department's information. However, you notice that the department's information does not match the information in the organization's official records.

What should you do?

Answers:

- Approve the CSR and issue the certificate.
- Reject the CSR and ask the department to submit a new one with correct information.
- Ignore the discrepancy and forward the CSR to the third-party CA.
- ***Investigate the discrepancy and verify the department's information before forwarding the CSR to the third-party CA.**

Explanation:

Investigating the discrepancy and verifying the department's information before forwarding the CSR to the third-party CA is the correct answer. As a security analyst, it's your responsibility to ensure the integrity of the organization's PKI. This includes verifying the information in CSRs before they are forwarded to the CA. Investigating the discrepancy and verifying the department's information ensures the CSR is legitimate and the certificate issued will be valid.

Approving the CSR and issuing the certificate without verifying the department's information can lead to security risks. The certificate could be used for malicious purposes.

While it's important to ensure the CSR contains correct information, simply rejecting the CSR without investigating the discrepancy could overlook potential security issues.

Forwarding the CSR to the third-party CA without addressing the discrepancy could result in the issuance of a certificate with incorrect information. This could lead to security vulnerabilities.

q_cert_types_csr_02_secp8

You are a network administrator for a large corporation. You receive a Certificate Signing Request (CSR) from a department within your organization. The CSR is for a new server that will be used to host sensitive company data.

The department has requested a Subject Alternative Name (SAN) certificate to cover multiple domains. However, you notice that one of the domains listed in the CSR is not owned by your organization.

What should you do?

Answers:

- Issue the SAN certificate as requested.
- ***Reject the CSR and ask the department to submit a new one without the unowned domain.**
- Issue the SAN certificate but exclude the unowned domain.
- Ignore the unowned domain and forward the CSR to the certificate authority (CA).

Explanation:

The CSR should be rejected and the department should be asked to submit a new one without the unowned domain. This ensures that the issued certificate only covers domains owned by your organization.

Issuing the SAN certificate as requested would mean including a domain not owned by your organization. This could lead to security risks and legal issues.

While it might seem like a good idea to issue the certificate and exclude the unowned domain, this could lead to confusion and potential security risks in the future. It's better to reject the CSR and ask for a new one to ensure the request is accurate and complete.

Ignoring the unowned domain and forwarding the CSR to the CA could result in the issuance of a certificate that includes a domain not owned by your organization. This could lead to security vulnerabilities and potential legal issues.

q_cert_types_org_validation_secp8

A medium-sized e-commerce company is planning to upgrade their website's security by acquiring a certificate from a certificate authority (CA).

The company wants to ensure that the certificate not only validates their domain ownership but also verifies the legitimacy of their organization. They are also looking for a validation process that can be completed within 1 to 3 days.

As the IT manager for the company, which level of CA validation would you recommend?

Answers:

- Domain validation
- ***Organization validation**
- Extended validation
- Self-signed certificate

Explanation:

Organization validation is the best choice because it requires the purchaser to prove they are a domain administrator and also prove the organization is legitimate. Additionally, these certificates can be issued in 1-3 days, which aligns with the company's requirement.

Domain validation only validates domain ownership and does not verify the legitimacy of the organization.

Extended validation provides a thorough validation process but it can take up to 5 days to be issued, which is longer than the company's preferred timeline.

Self-signed certificate does not provide the same protection and security as a CA-validated certificate and is not recommended for an e-commerce company like the one in the scenario.

q_cert_types_san_cert_secp8

John is a network administrator for a growing company, XYZ Corp, which has recently acquired two smaller companies, ABC Corp and DEF Corp.

Each company has its own domain: xyz.com, abc.net, and def.org. John needs to secure all three domains with a single certificate to simplify management and reduce costs. He also wants to ensure that the certificate is issued by a trusted certificate authority (CA) to avoid trust issues with web browsers.

Which type of certificate should John choose?

Answers:

- Root certificate
- ***Subject Alternative Name (SAN) certificate**
- Wildcard certificate
- Self-signed certificate

Explanation:

A Subject Alternative Name (SAN) certificate is the correct answer. A SAN certificate allows an organization to cover multiple domains with one certificate. This is exactly what John needs to secure all three domains (xyz.com, abc.net, def.org) with a single certificate.

A root certificate is the first certificate that a certificate authority (CA) creates and is used to sign lower-level certificates. It is not suitable for John's needs as it does not cover multiple domains.

While a wildcard certificate can cover one domain and multiple subdomains, it cannot cover multiple domains. Therefore, it would not meet John's needs to secure all three domains with one certificate.

A self-signed certificate is not issued by a trusted CA and would likely cause trust issues with web browsers. This would not meet John's requirement for the certificate to be issued by a trusted CA.

q_cert_types_wildcard_secp8

The network administrator for an international e-commerce company that operates multiple online stores must ensure secure communication across various subdomains.

To streamline secure sockets layer/transport layer security (SSL/TLS) certificate management and implement a robust public key infrastructure (PKI), the network administrator must identify the most suitable solution for efficiently securing the company's numerous subdomains within the PKI.

What is the MOST suitable solution for efficiently securing the multiple subdomains of the company's online stores within the PKI?

Answers:

- ***Wildcard certificates**
- Self-signed certificates
- Certificate revocation lists (CRLs)
- Certificate pinning

Explanation:

By using wildcard certificates, the company can secure all subdomains under a single certificate, ensuring efficient management and reducing administrative overhead. Wildcard certificates streamline the certificate deployment process and simplify ongoing maintenance tasks, leading to improved operational efficiency.

Self-signed certificates lack the trust and validation provided by a reputable certificate authority.

Certificate revocation lists (CRLs) provide information about revoked certificates but do not address the efficient management of multiple subdomains.

Certificate pinning is a mechanism to ensure trust in specific certificates but not specifically designed to manage multiple subdomains within a PKI efficiently.

q_cert_concepts_crl_01_secp8

A private key has been stolen. Which action should you take to deal with this crisis?

Answers:

- Delete the public key
- ***Add the digital certificate to the CRL**
- Place the private key in escrow
- Recover the private key from escrow

Explanation:

If a private key--a digital certificate or digital signature--is compromised (especially by theft), it should be added to the CRL. This prevents any future use of the key/certificate and prevents impersonation attacks.

There is no need to delete the public key because CRLs deal with any attempted use of the private key. The private key should have been placed in escrow at the beginning of its lifetime if key recovery was desired. In this situation, key recovery is not necessary.

q_cert_concepts_crl_02_secp8

Which action is taken when the private key associated with a digital certificate becomes compromised?

Answers:

- ***The compromised digital certificate is added to the certificate revocation list (CRL).**
- The compromised digital certificate is reissued with the same private key.
- The compromised digital certificate is ignored and continues to be used.
- The compromised digital certificate is deleted from the system.

Explanation:

The correct answer is that the compromised digital certificate is added to the certificate revocation list (CRL). A CRL is a list of digital certificates that have been revoked by the issuing certificate authority (CA) before their scheduled expiration date and should no longer be trusted. When a private key associated with a digital certificate becomes compromised, the certificate is added to the CRL to ensure that it is no longer trusted by any systems or users.

Reissuing the compromised digital certificate with the same private key would not solve the problem. The private key has been compromised, meaning unauthorized individuals may have access to it. Using the same private key would continue to leave the certificate and any associated systems or data vulnerable to misuse.

Ignoring the compromise and continuing to use the digital certificate would be a serious security risk. The compromised private key could be used by unauthorized individuals to impersonate the certificate holder, decrypt sensitive data, or perform other malicious activities.

Simply deleting the compromised digital certificate from the system would not be sufficient to address the issue. Other systems or users that trust the certificate would not be aware of the compromise and could continue to trust the certificate if they encounter it. The certificate needs to be revoked and added to the CRL to ensure it is no longer trusted.

q_cert_concepts_crl_attributes_secp8

Which of the following are attributes of a certificate revocation list (CRL)? (Select two.)

Answers:

- ***Publish period**
- ***Distribution point(s)**
- Validity period
- Certificate authority
- Encryption algorithm

Explanation:

The following are attributes of a certificate revocation list (CRL):

- Publish period - This is the date and time on which the CRL is published. Most CAs are set up to publish the CRL automatically.
- Distribution point(s) - These are the location(s) to which the CRL is published.

The following are *not* attributes of a Certificate Revocation List (CRL):

- Certificate authority - While the CA is responsible for creating and managing the CRL, it is not an attribute of the CRL itself.
- Encryption algorithm - This is not an attribute of the CRL. It is a method used to secure data, not a characteristic of the CRL.

- Validity period - This is a common misconception. While it seems logical that a CRL would have a validity period, in reality, the CRL is continuously updated and does not have a set validity period. Instead, each individual certificate within the CRL has its own validity period.

q_cert_concepts_escrow_01_secp8

What is the purpose of key escrow?

Answers:

- ***Key escrow is a method of storing a copy of the encryption key with a trusted third party.**
- Key escrow is a method of generating encryption keys.
- Key escrow is a method of transmitting encryption keys over the internet.
- Key escrow is a method of revoking encryption keys.

Explanation:

The correct answer is that key escrow is a method of storing a copy of the encryption key with a trusted third party. Key escrow is a security measure where a copy of the encryption key is stored with a trusted third party. This is often done for security and legal purposes. In case the original key is lost or the key holder is unavailable, the key can be retrieved from the escrow to access the encrypted data.

Key escrow does not involve the generation of encryption keys. It is a method for storing a copy of the encryption key with a trusted third party for safekeeping and retrieval in case of need.

Key escrow is not a method for transmitting encryption keys. It is a method of storing a copy of the encryption key with a trusted third party. The transmission of encryption keys involves different protocols and methods to ensure security.

Key escrow does not involve the revocation of encryption keys. It is a method of storing a copy of the encryption key with a trusted third party. The revocation of encryption keys is a separate process that involves invalidating the key and ceasing its use for encryption or decryption.

q_cert_concepts_escrow_02_secp8

You are concerned that if a private key is lost, all documents encrypted with your private key will be inaccessible.

Which service should you use to solve this problem?

Answers:

- ***Key escrow**
- OCSP
- RA
- CSP

Explanation:

Key escrow backs up private keys to a third-party organization outside of the company. If the private key is lost, you can recover the key from escrow.

Online Certificate Status Protocol (OCSP) is a protocol used to check the status of an individual digital certificate to verify whether it is good or has been revoked.

A cryptographic service provider (CSP) resides on the client and generates the key pair.

A registration authority (RA) verifies the information included in a certificate request.

q_cert_concepts_escrow_03_secp8

A network administrator responsible for managing the encryption keys used in the organization's secure communications had a new key management policy implemented by the organization, which included a provision for key escrow.

The administrator understands the role of key escrows in relation to private keys.

Which of the following BEST describes the purpose of key escrow in the context of private keys?

Answers:

- ***Key escrow involves securely storing a copy of the private key with a trusted third party for recovery purposes, ensuring availability in case of key loss or compromise.**
- Key escrow refers to the process of encrypting the private key to prevent unauthorized access and protect it from disclosure.
- Key escrow enables the distribution of private keys to multiple users within the organization to enhance key redundancy and reliability.
- Key escrow involves periodically rotating the private key to maintain data integrity and prevent cryptographic attacks.

Explanation:

Key escrow involves securely storing a copy of the private key with a trusted third party for recovery and availability in case of key loss or compromise. Key escrow serves as a backup mechanism for private keys.

Key escrow does not primarily involve encrypting the private key. The primary purpose of key escrow is key recovery and availability.

Key escrow does not facilitate the distribution of private keys to multiple users for redundancy and reliability.

Key escrow does not involve the periodic rotation of private keys. The primary purpose does not relate to data integrity or preventing cryptographic attacks.

q_cert_concepts_root_of_trust_secp8

Which of the following statements accurately describes the root of trust model in a public key infrastructure (PKI)?

Answers:

- The root of trust model involves multiple root certificates, each issued by a different certificate authority (CA).
- In the root of trust model, the root certificate is issued by a third-party CA, not the organization's own CA.
- ***The root of trust model defines how users and different CAs can trust one another, with each CA issuing itself a root certificate.**
- The root of trust model involves a root certificate that is issued by a user, not a CA.

Explanation:

The root of trust model defines how users and different CAs can trust one another, with each CA issuing itself a root certificate is the correct answer. The root of trust model defines how users and different CAs can trust one another, with each CA issuing itself a root certificate. This is the core concept of the root of trust model, where the root certificate is self-signed by the CA, and installing the CA's root certificate means that hosts will automatically trust any certificates signed by that CA.

The root of trust model involves multiple root certificates, each issued by a different certificate authority (CA) is incorrect because in the root of trust model, there is typically one root certificate that is self-signed by the CA.

In the root of trust model, the root certificate is issued by a third-party CA, not the organization's own CA is incorrect because in the root of trust model, the root certificate is self-signed by the CA itself, not a third-party CA.

The root of trust model involves a root certificate that is issued by a user, not a CA is incorrect because in the root of trust model, the root certificate is issued by the CA, not a user.

q_cert_concepts_single_ca_secp8

Which of the following statements accurately describes the single certificate authority (CA) model in a public key infrastructure (PKI)?

Answers:

- In the single CA model, the root CA issues certificates to multiple intermediate CAs.
- The single CA model is often used in large, complex networks due to its scalability.
- ***In the single CA model, a single root CA issues certificates directly to users and computers.**
- The single CA model is highly secure and if the CA server is compromised, it does not affect the entire PKI.

Explanation:

In the single CA model, a single root CA issues certificates directly to users and computers. This is a simple model often used on private networks where there is no need for intermediate CAs.

In the single CA model, the root CA issues certificates to multiple intermediate CAs is incorrect because in the single CA model, the root CA issues certificates directly to users and computers, not to intermediate CAs.

The single CA model is often used in large, complex networks due to its scalability is incorrect because the single CA model is typically used in smaller, private networks due to its simplicity, not in large, complex networks.

The single CA model is highly secure and if the CA server is compromised, it does not affect the entire PKI is incorrect because if the single CA server is compromised in this model, the entire PKI is affected as all certificates are issued directly by this CA.

q_cert_concepts_third-party_ca_secp8

You are a security manager for a mid-sized company and are considering using a third-party certificate authority (CA) to manage your company's certificates.

Which of the following would be the MOST significant benefit of using a third-party CA?

Answers:

- It would allow your company to issue its own root certificates.
- It would eliminate the need for your company to manage any certificates.

- ***It would allow your company to set up different certificate policies through intermediate CAs.**
- It would make your company's certificates immune to revocation.

Explanation:

It would allow your company to set up different certificate policies through intermediate CAs is the correct answer. Third-party CAs often operate a hierarchical model where the root CA issues certificates to one or more intermediate CAs. This allows for different certificate policies, enabling clear understanding of what a particular certificate is designed for.

It would allow your company to issue its own root certificates is incorrect because when using a third-party CA, the CA issues the root certificates, not the company.

It would eliminate the need for your company to manage any certificates is incorrect because even when using a third-party CA, the company still needs to manage the certificates issued to its users and computers.

It would make your company's certificates immune to revocation is incorrect because all certificates, regardless of who issues them, can be revoked if necessary.

4.0 Identity and Access Management

4.1 Access Control Models

As you study this section, answer the following questions:

- What is access control and why is it important?
- How are rule-based access control and mandatory access control (MAC) similar?
- How does role-based control differ from rule-based control?
- How do separation of duties and job rotation differ?
- Which authentication type requires you to prove your identity?

The key terms for this section include:

Term	Definition
CIA Triad	Three principles of security control and management - confidentiality, integrity, and accessibility. Also known as the information security triad.
Confidentiality	The fundamental security goal of keeping information and communications private and protecting them from unauthorized access.
Integrity	The fundamental security goal of keeping organizational information accurate, free of errors, and without unauthorized modifications.
Availability	The fundamental security goal of ensuring that computer systems operate continuously and that authorized persons can access data that they need.
Non-repudiation	The security goal of ensuring that the party that sent a transmission or created data remains associated with that data and cannot deny sending or creating that data.
National Institute of Standards and Technology (NIST)	Develops computer security standards used by US federal agencies and publishes cybersecurity best practice guides and research.
cybersecurity frameworks (CSF)	Standards, best practices, and guidelines for effective security risk management. Some frameworks are general in nature, while others are specific to industry or technology types.
security controls	A technology or procedure put in place to mitigate vulnerabilities and risk and to ensure the confidentiality, integrity, and availability (CIA) of information.

Gap analysis	An analysis that measures the difference between the current and desired states in order to help assess the scope of work included in a project.
identity and access management (IAM)	A security process that provides identification, authentication, and authorization mechanisms for users, computers, and other entities to work with organizational assets like networks, operating systems, and applications.
Identification	The process by which a user account (and its credentials) is issued to the correct person. Sometimes referred to as enrollment.
Authentication	A method of validating a particular entity's or individual's unique credentials.
Authorization	The process of determining what rights and privileges a particular entity has.
Accounting	Tracking authorized usage of a resource or use of rights by a subject and alerting when unauthorized use is detected or attempted.
authentication, authorization, and accounting (AAA)	A security concept where a centralized platform verifies subject identification, ensures the subject is assigned relevant permissions, and then logs these actions to create an audit trail.
control plane	In zero trust architecture, functions that define policy and determine access decisions.
permissions	Security settings that control access to objects including file system items and network resources.
Discretionary access control (DAC)	An access control model where each resource is protected by an access control list (ACL) managed by the resource's owner (or owners).
Mandatory access control (MAC)	An access control model where resources are protected by inflexible, system-defined rules. Resources (objects) and users (subjects) are allocated a clearance level (or label).
Role-based access control (RBAC)	An access control model where resources are protected by ACLs that are managed by administrators and that provide user permissions based on job functions.
group account	A group account is a collection of user accounts that is useful when establishing file permissions and user rights because when many individuals need the same level of access, a group could be established containing all the relevant users.

Attribute-based access control (ABAC)	An access control technique that evaluates a set of attributes that each subject possesses to determine if access should be granted.
Rule-based access control	A nondiscretionary access control technique that is based on a set of operational rules or restrictions to enforce a least privileges permissions policy.
Least privilege	A basic principle of security stating that something should be allocated the minimum necessary rights, privileges, or information to perform its role.
Provisioning	The process of deploying an account, host, or application to a target production environment. This involves proving the identity or integrity of the resource, and issuing it with credentials and access permissions.
Deprovisioning	The process of removing an account, host, or application from the production environment. This requires revoking any privileged access that had been assigned to the object.
security identifier (SID)	The value assigned to an account by Windows and that is used by the operating system to identify that account.
group policy objects (GPOs)	On a Windows domain, a way to deploy per-user and per-computer settings such as password policy, account restrictions, firewall status, and so on.
geolocation	The identification or estimation of the physical location of an object, such as a radar source, mobile phone, or Internet-connected computing device.
time-of-day restrictions policy	Policies or configuration settings that limit a user's access to resources.

4.1.1 Fundamental Security Concepts (Lesson Video)

Transcript:

In this lesson, we'll look at fundamental concepts that underpin the world of information security. Let's dive in.

Information security, often referred to as "infosec," is all about safeguarding data resources from unauthorized access, attacks, theft, or damage. Data can be vulnerable at rest, in transit, or during processing.

To ensure secure information, we focus on confidentiality, integrity, and availability. To balance these needs, we use the CIA Triad. First, Confidentiality. This means that information can only be accessed by authorized individuals. Second, Integrity ensures that data remains unaltered and is only modified by authorized parties. And third, Availability. This means information must be readily accessible to those authorized to use it. These three principles form the backbone of information security, and as security specialists, you'll find you're always seeking the best balance of all three components.

An access control system ensures that an information system meets the goals of the CIA triad. Access control dictates how subjects (like users, devices, or processes) interact with objects (like networks, servers, databases, apps, or files). Modern access control is implemented through Identity and Access Management, or IAM, consisting of four main processes: Identification—here, we create unique accounts for users, devices, or processes; Authentication—this is the process of proving the identity of subjects through credentials; Authorization—this determines and enforces rights for subjects on resources; and Accounting—this is the tracking of authorized resource usage and the detection of unauthorized access. Access control is essential for both people and systems, ensuring that only legitimate actions are permitted.

Some security models and researchers identify other properties of secure systems. The most important of these is non-repudiation. Non-repudiation means a person can't deny doing something, such as creating, modifying, or sending a resource.

For example, providing proof of authenticity and integrity of data that's sent or received.

Gap analysis is a process that assesses how well an organization's security systems align with a cybersecurity framework. Security functions have specific goals achieved through security controls. To select the right controls, organizations use frameworks to guide them.

Frameworks provide structure and guidance for security programs. Gap analysis identifies deviations from framework requirements and recommends remediation, thus helping organizations maintain cybersecurity, meet compliance requirements, and prioritize investments.

Zero Trust is a security model that treats all devices, users, and services as untrusted, regardless of location within or outside the network's perimeter.

This model relies on fundamental concepts for comprehensive security. These include adaptive identity, threat score reduction, and policy-driven access control. Adaptive identity recognizes that identities change and need continuous verification. Threat scope reduction limits access to resources on a need-to-know basis, reducing attack surfaces. Policy-driven access control enforces access restrictions based on user identity, device posture, and network context.

Zero Trust separates the control plane and data plane for flexibility and scalability. In a Zero Trust architecture, the control plane manages policies and authorization, while the data plane handles secure data transfer.

The control plane defines access policies, monitors for threats, and updates policies. The data plane establishes secure data pathways and enforces access policies. Separating these planes enhances flexibility and security, allowing for granular control and continuous monitoring.

And that's it for this lesson. In this lesson, we introduced you to fundamental information security concepts. We first looked at information security applied through the CIA Triad. Then, we discussed access control, which establishes how subjects interact with objects in a system. Next, we talked about gap analysis and how it helps you know where to improve your security programs. We finished this lesson by reviewing Zero Trust security concepts and how those concepts are applied through control planes and data planes in a Zero Trust model.

4.1.2 Access Control Facts

This lesson covers the following topics:

- Information security
- Cybersecurity framework
- Gap analysis
- Access control
- Zero Trust security concepts
- Control and data planes in Zero Trust models

Information Security

Information security (infosec) refers to the protection of data resources from unauthorized access, attack, theft, or damage. Data may be vulnerable because of the way it is stored, transferred, or processed. The systems used to store, transmit, and process data must demonstrate the properties of security. Secure information has three properties, often referred to as the CIA Triad :

- **Confidentiality** means that information can only be read by people who have been explicitly authorized to access it.
- **Integrity** means that the data is stored and transferred as intended and that any modification is authorized.
- **Availability** means that information is readily accessible to those authorized to view or modify it.

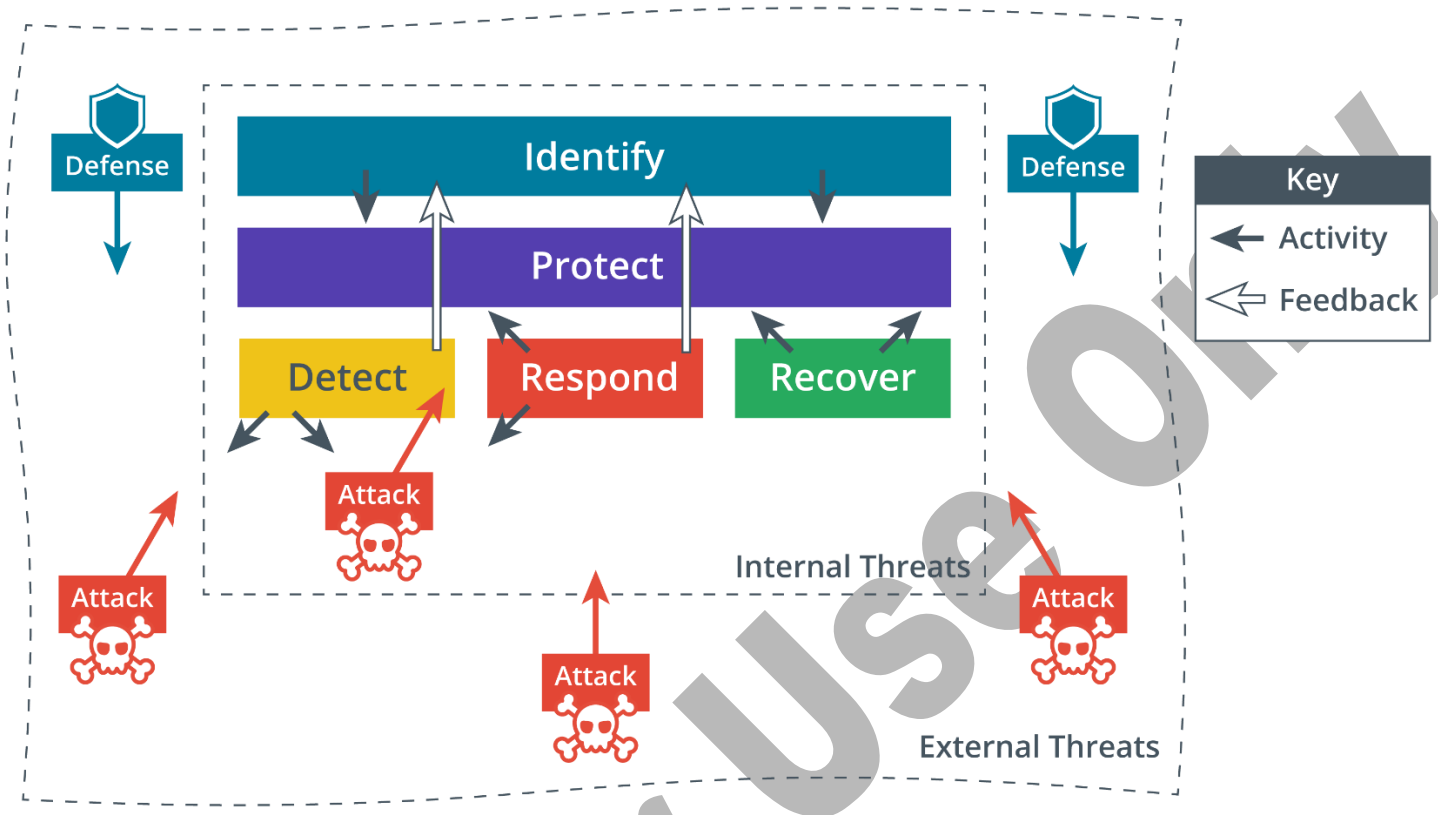
The triad can also be referred to as "AIC" to avoid confusion with the Central Intelligence Agency.

Some security models and researchers identify other properties of secure systems. The most important of these is non-repudiation. Non-repudiation means that a person cannot deny doing something, such as creating, modifying, or sending a resource. For example, a legal document, such as a will, must usually be witnessed when it is signed. If there is a dispute about whether the document was correctly executed, the witness can provide evidence that it was.

Cybersecurity Framework

Within the goal of ensuring information security, cybersecurity refers specifically to provisioning secure processing hardware and software. Information security and cybersecurity tasks can be classified into five functions, following the framework developed by the National Institute of Standards and Technology (NIST) (nist.gov/cyberframework/online-learning/five-functions):

- **Identify** — develop security policies and capabilities. Evaluate risks, threats, and vulnerabilities and recommend security controls to mitigate them.
- **Protect** — procure/develop, install, operate, and decommission IT hardware and software assets with security as an embedded requirement of every stage of this operation's lifecycle.
- **Detect** — perform ongoing, proactive monitoring to ensure that controls are effective and capable of protecting against new types of threats.
- **Respond** — identify, analyze, contain, and eradicate threats to systems and data security.
- **Recover** — implement cybersecurity resilience to restore systems and data if other controls are unable to prevent attacks.



Core cybersecurity tasks.

NIST's framework is just one example. There are many other cybersecurity frameworks (CSF) .

Gap Analysis

Each security function is associated with a number of goals or outcomes. For example, one outcome of the Identify Function is an inventory of the assets owned and operated by the company. Outcomes are achieved by implementing one or more security controls .

Numerous categories and types of security controls cover a huge range of functions. This makes the selection of appropriate and effective controls difficult.

A cybersecurity framework guides the selection and configuration of controls. Frameworks are important because they save an organization from building its security program in a vacuum or building it on a foundation that fails to account for important security concepts.

The use of a framework allows an organization to make an objective statement of its current cybersecurity capabilities, identify a target level of capability, and prioritize investments to achieve that target. This gives a structure to internal risk management procedures and provides an externally verifiable statement of regulatory compliance.

Gap analysis is a process that identifies how an organization's security systems deviate from those required or recommended by a framework. This will be performed when first adopting a framework or when meeting a new industry or legal compliance requirement. The analysis might be repeated every few years to meet compliance requirements or to validate any changes that have been made to the framework.

For each section of the framework, a gap analysis report will provide an overall score, a detailed list of missing or poorly configured controls associated with that section, and recommendations for remediation.

Function	Controls (Actual/Required)	CIA Triad Risk Levels	Target Remediation
Identify (10/16)	Asset Management (4/6)	C : 6 I : 6 A : 6	Q4
	Governance (3/4)	C : 6 I : 6 A : 1	Q3
	Risk Assessment (3/6)	C : 6 I : 6 A : 3	Q3
Protect (8/16)	Identity and Access Management (5/8)	C : 9 I : 9 A : 4	Q1
	Data Security (3/8)	C : 9 I : 9 A : 4	Q1

Advanced capability
Intermediate capability
No/basic capability

Summary of gap analysis findings showing the number of recommended controls not implemented per function and category, plus risks to confidentiality, integrity, and availability from missing controls and target remediation date.

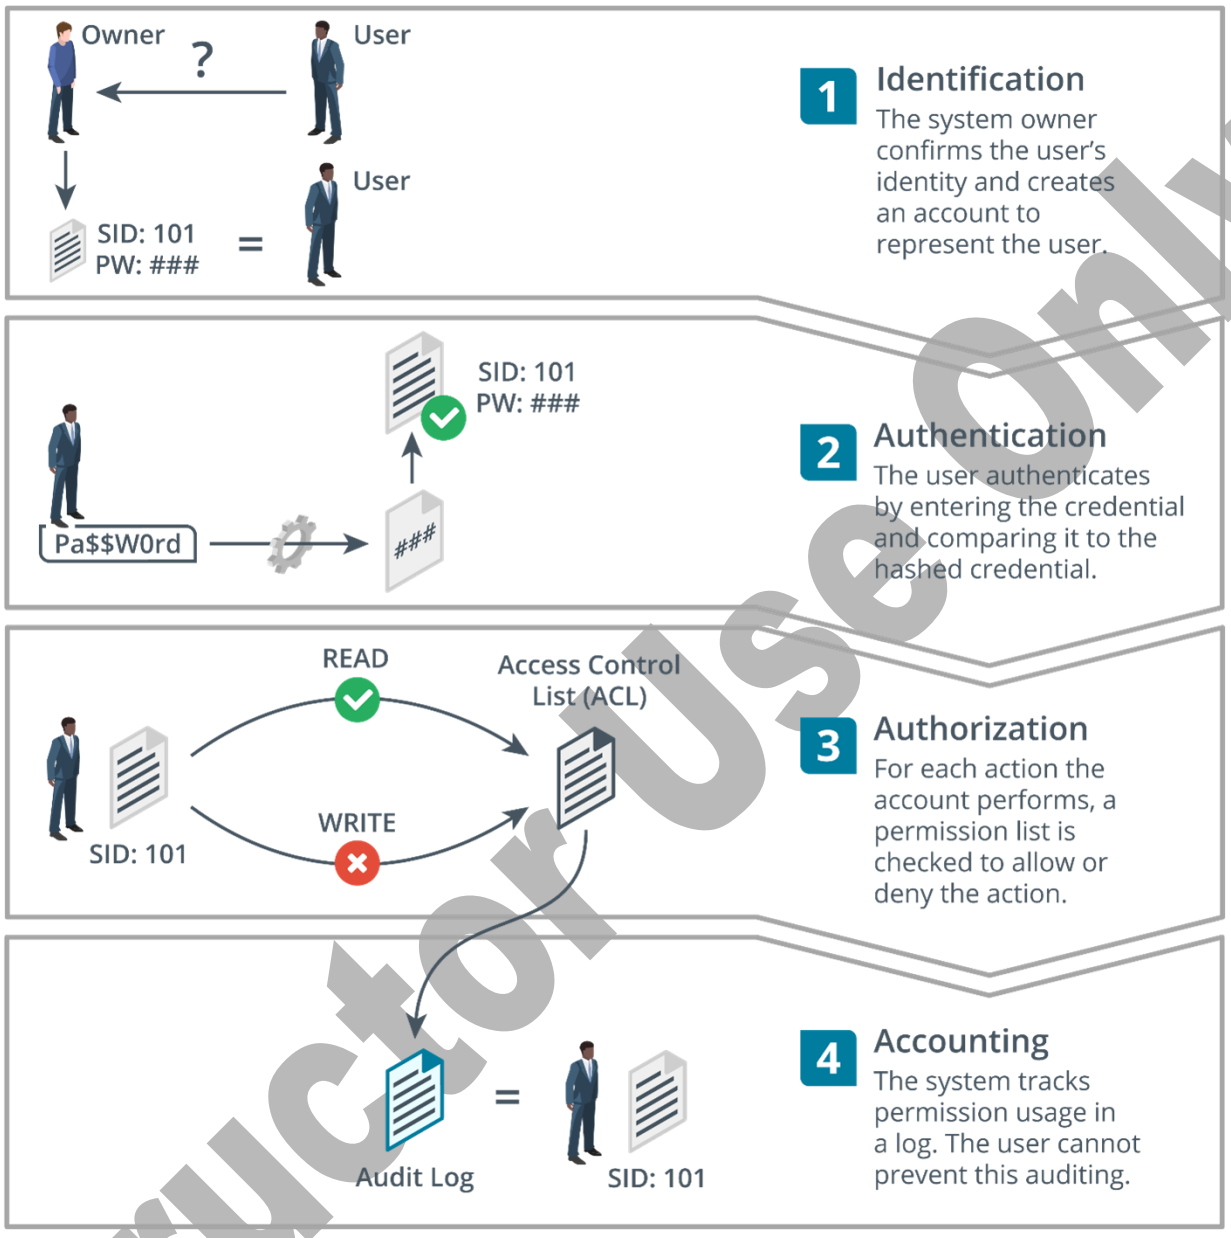
While some or all work involved in gap analysis could be performed by the internal security team, a gap analysis is likely to involve third-party consultants. Frameworks and compliance requirements from regulations and legislation can be complex enough to require a specialist. Advice and feedback from an external party can alert the internal security team to oversights, new trends, and changes in best practices.

Access Control

An access control system ensures that an information system meets the goals of the CIA triad. Access control governs how subjects/principals may interact with objects. Subjects are people, devices, software processes, or any other system that can request and be granted access to a resource. Objects are the resources. An object could be a network, server, database, app, or file. Subjects are assigned rights or permissions on resources.

Modern access control is typically implemented as an identity and access management (IAM) system. IAM comprises four main processes:

- **Identification** — creating an account or ID that uniquely represents the user, device, or process on the network.
- **Authentication** — proving that a subject is who or what it claims to be when it attempts to access the resource. An authentication factor determines what sort of credential the subject can use. For example, people might be authenticated by providing a password; a computer system could be authenticated using a token such as a digital certificate.
- **Authorization** — determining what rights subjects should have on each resource and enforcing those rights. An authorization model determines how these rights are granted. For example, in a discretionary model, the object owner can allocate rights. In a mandatory model, rights are predetermined by system-enforced rules and cannot be changed by any user within the system.
- **Accounting** — tracking authorized usage of a resource or use of rights by a subject and alerting when unauthorized use is detected or attempted.



Differences among identification, authentication, authorization, and accounting. (Images © 123RF.com.)

The servers and protocols that implement these functions can also be referred to as authentication, authorization, and accounting (AAA) . The use of IAM to describe enterprise security workflows is becoming more prevalent as the importance of the identification process is better acknowledged.

For example, if you are setting up an e-commerce site and want to enroll users, you need to select the appropriate controls to perform each function:

- **Identification** — ensure that customers are legitimate. For example, you might need to ensure that billing and delivery addresses match and that they are not trying to use fraudulent payment methods.
- **Authentication** — ensure that customers have unique accounts and that only they can manage their orders and billing information.

- **Authorization** — rules to ensure customers can place orders only when they have valid payment mechanisms in place. You might operate loyalty schemes or promotions that authorize certain customers to view unique offers or content.
- **Accounting** — the system must record the actions a customer takes (to ensure that they cannot deny placing an order, for instance).

Remember that these processes apply both to people and to systems. For example, you need to ensure that your e-commerce server can authenticate its identity when customers connect to it using a web browser.

Zero Trust Security Concepts

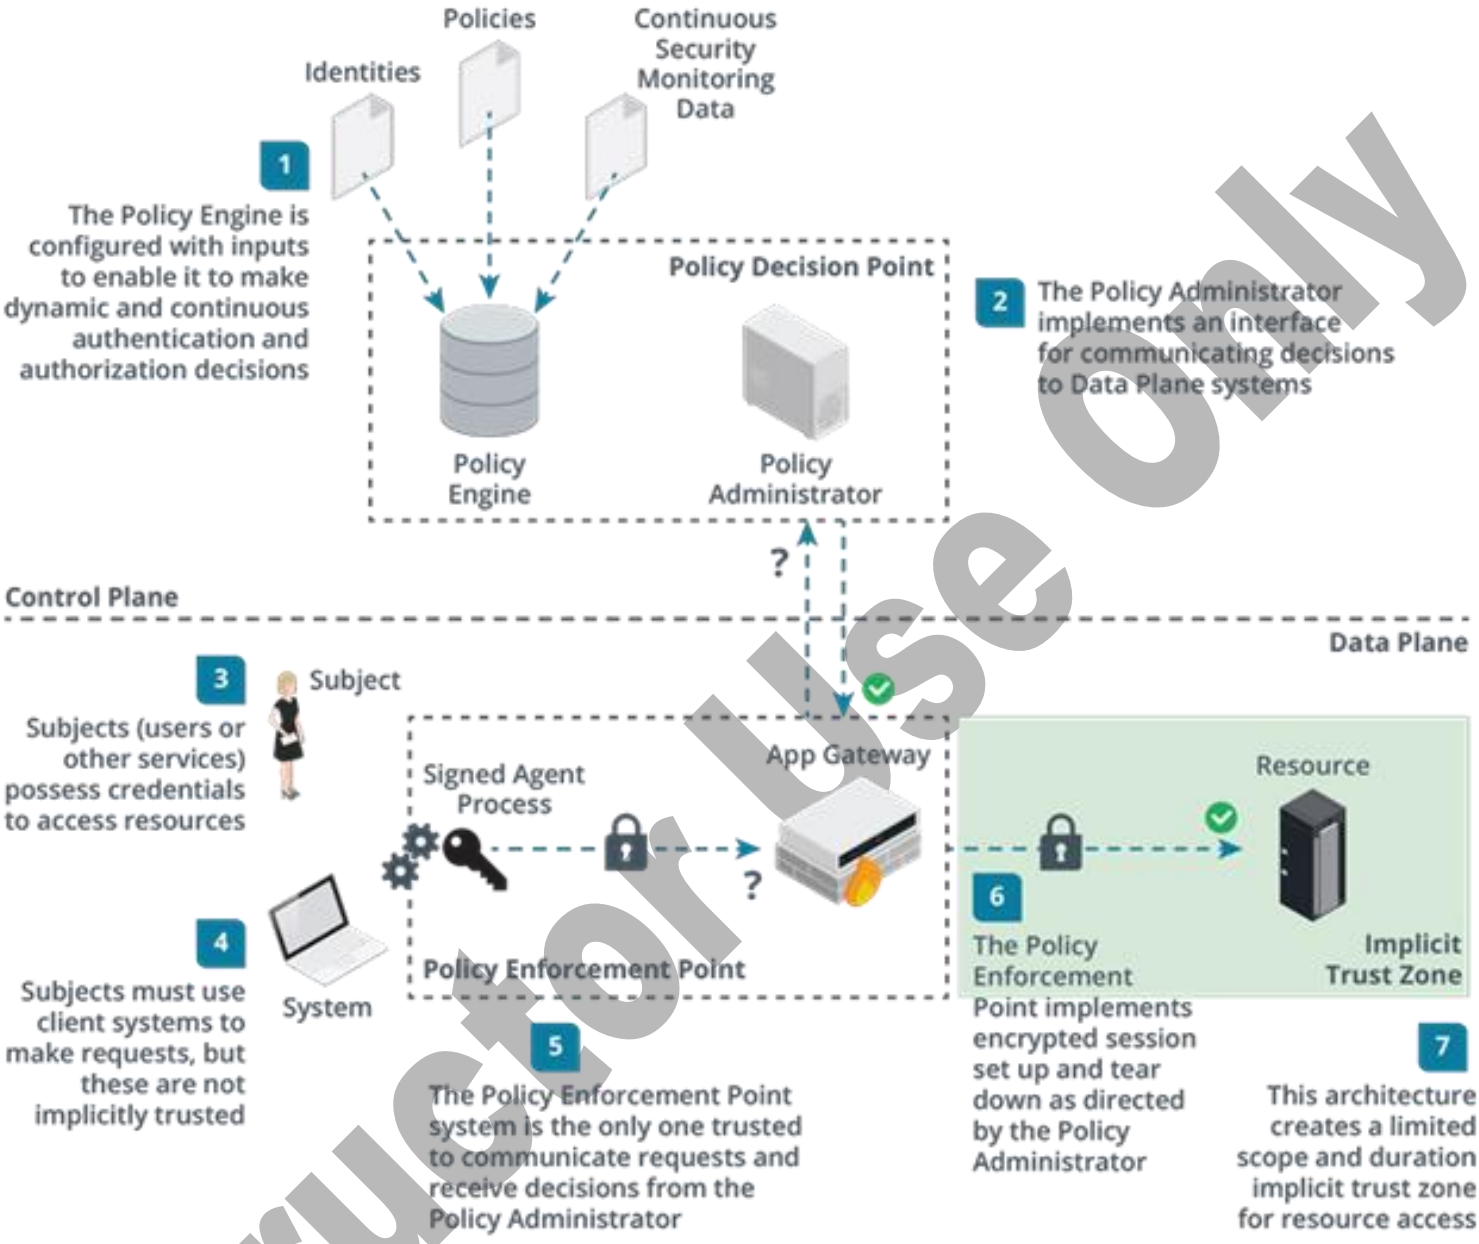
Zero Trust is a security model that assumes that all devices, users, and services are not inherently trusted, regardless of whether inside or outside a network's perimeter. Instead, the Zero Trust model requires all users and devices to be authenticated and authorized before accessing network resources. The Zero Trust model includes several fundamental concepts that provide a comprehensive security solution.

- **Adaptive identity** recognizes that user identities are not static and that identity verification must be continuous and based on a user's current context and the resources they are attempting to access.
- **Threat scope reduction** means that access to network resources is granted on a need-to-know basis, and access is limited to only those resources required to complete a specific task. This concept reduces the network's attack surface and limits the damage a successful attack can cause.
- **Policy-driven access control** describes how access control policies are used to enforce access restrictions based on user identity, device posture, and network context.

Device posture refers to the security status of a device, including its security configurations, software versions, and patch levels. In a security context, device posture assessment involves evaluating the security status of a device to determine whether it meets certain security requirements or poses a risk to the network.

Control and Data Planes in Zero Trust Models

In a Zero Trust architecture, the control and data planes are implemented separately and have different functions.



Components in NIST's Zero Trust architecture framework.

The control plane manages policies that dictate how users and devices are authorized to access network resources. It is implemented through a centralized policy decision point. The policy decision point is responsible for defining policies that limit access to resources on a need-to-know basis, monitoring network activity for suspicious behavior, and updating policies to reflect changing network conditions and security threats. The policy decision point is comprised of two subsystems:

- The policy engine is configured with subject and host identities and credentials, access control policies, up-to-date threat intelligence, behavioral analytics, and other results of host and network security scanning and monitoring. This comprehensive state data allows it to define an algorithm and metrics for making dynamic authentication and authorization decisions on a per-request basis.
- The policy administrator is responsible for managing the process of issuing access tokens and establishing or tearing down sessions based on the decisions made by the policy engine. The policy administrator implements an interface between the control and the data plane.

Where systems in the control plane define policies and make decisions, systems in the data plane establish sessions for secure information transfers. In the data plane, a subject (user or service) uses a system (such as a client host PC, laptop, or smartphone) to make requests for a given resource. A resource is typically an enterprise app running on a server or cloud. Each request is mediated by a policy enforcement point. The enforcement point might be implemented as a software agent running on the client host that communicates with an app gateway. The policy enforcement point interfaces with the policy administrator to set up a secure data pathway if access is approved or tear down a session if access is denied or revoked.

The processes implementing the policy enforcement point are the only ones permitted to interface with the policy administrator. It is critical to establish a root of trust for these processes so that policy decisions cannot be tampered with.

The data pathway established between the policy enforcement point and the resource is referred to as an implicit trust zone. For example, the outcome of a successful access request might be an IPsec tunnel established between a digitally signed agent process running on the client, a trusted web application gateway, and the resource server. Because the data is protected by IPsec transport encryption, no tampering by anyone with access to the underlying network infrastructure (switches, access points, routers, and firewalls) is possible.

The goal of Zero Trust design is to make this implicit trust zone as small as possible and as transient as possible. Trusted sessions might only be established for individual transactions. This granular or microsegmented approach is in contrast with perimeter-based models, where trust is assumed once a user has authenticated and joined the network. In Zero Trust, place in the network is not a sufficient reason to trust a subject request. Similarly, even if a user is nominally authenticated, behavioral analytics might cause a request to be blocked or a session to be terminated.

Separating the control and data plane is significant because it allows for a more flexible and scalable network architecture. The centralized control plane ensures consistency for access request handling across both the managed enterprise network and unmanaged internet or third-party networks, regardless of the devices being used or the user's location. This makes managing access control policies and monitoring network activity for suspicious behavior easier. Continuous monitoring via the independent control plane means that sessions can be terminated if anomalous behavior is detected.

4.1.3 Access Control Best Practices

Access control refers to regulating and managing the permissions granted to individuals, software, systems, and networks to access resources or information. Access controls ensure that only authorized entities can perform specific actions or access certain data, while unauthorized entities are denied access. Access control concepts apply to networks, physical access, data, applications, and the cloud.

This lesson covers the following topics:

- Access control best practices
- Transition best practices

Access Control Best Practices

Access control best practices take into consideration the following security principles and concepts:

Principle	Description
Principle of least privilege	Implementing the principle of least privilege (PoLP) is a cornerstone of improving endpoint protection and minimizing the risk of security issues. The principle of least privilege dictates that users, applications, and processes should only be granted the minimum permissions necessary to complete their duties and nothing more.

Principle	Description
	There are several practical methods for implementing least privilege. An essential first step to effectively implementing least privilege is thoroughly auditing user roles, privileges, and responsibilities. This process allows organizations to understand what access each user needs to perform their job role effectively. Access controls and permissions can be adjusted to adopt a principle of least privilege that best reflects the audit results. User and account management tools are also essential when implementing the principle of least privilege. Regularly reviewing and removing unused or unnecessary accounts reduces the potential targets for an attacker. Similarly, temporary privileges, which grant additional access rights for a limited time and only when required, can help keep privileges as restrictive as possible. The principle of least privilege also applies to software applications and operating systems, not just to users. For instance, ensuring that applications run with the minimum necessary permissions can prevent them from being exploited to carry out privileged actions. Common methods of controlling access include: • *Implicit deny* denies access to users or groups not explicitly given access to a resource. Implicit deny is the weakest form of privilege control. • *Explicit allow* specifically identifies users or groups who have access. Explicit allow is a moderate form of access control in which privilege has been granted to a subject. • *Explicit deny* identifies users or groups who are not allowed access. Explicit deny is the most robust access control, overruling all other privileges granted.
Need to know	Need to know describes the restriction of highly sensitive data usually referenced in government and military contexts. Essential facts about the need to know include: • Even if an individual is fully cleared, the information will not be divulged unless the person needs to know the information to perform official duties. • Need to know discourages casual browsing of sensitive materials. • In a classified environment, a clearance into a top-secret compartment allows access to only specific information. This is a form of mandatory access control (MAC).
Separation of duties	Separation of duties is the concept of having more than one person required to complete a task. This is a preventive principle primarily designed to reduce conflicts of interest. It also prevents insider attacks because no one person has end-to-end control, and no one person is irreplaceable. Essential facts to know about separation of duties include: • A business can use the principle of split knowledge to achieve a separation of duties. This means no single person controls a system's security mechanisms; no single person can completely compromise the system. • In sensitive or high-risk transactions, a business can use two-man controls. This means that two operators must review and approve each other's work.
Job rotation	Job rotation is a technique where users are cross-trained in multiple positions. Responsibilities are regularly rotated between personnel. Job rotation:

Principle	Description
	• Cross trains staff in different functional areas to detect fraud. • Exchanges positions of two or more employees to allow for oversight of past transactions. • Can be used for training purposes.
Defense-in-depth	Defense-in-depth is an access control principle that implements multiple access control methods instead of relying on a single process. Numerous defenses make it harder to bypass security measures.
Identification	Identification is claiming an identity, such as telling someone your name. Essential facts to know about identification include: • A username is a form of identification. • Identification is not very secure because anyone could pretend to be the user. • To substantiate identity, the person must provide some form of identity verification.
Multi-Factor Authentication	Multi-Factor Authentication is using more than one way to verify identity. Multi-Factor Authentication is achieved by requiring two or more methods that only the user can provide. Five categories of computer system authentication include: • *Something you are* , such as biometric information (e.g., fingerprint or retina scan). • *Something you have* , such as smart cards, RSA tokens, or security key fobs. • *Something you know* , such as passwords and PINs. • *Somewhere you are* , such as a geographical location. • *Something you do* , such as how you type a sentence on a keyboard.
Mutual authentication	Mutual authentication is when two communicating entities authenticate each other before exchanging data. It requires not only the server to authenticate the user but the user to authenticate the server. This makes mutual authentication more secure than traditional, one-way authentication.
Time of day restrictions	Time of day restrictions impose restrictions on incoming and outgoing network traffic based on the time of day. This allows organizations to define when resources can be accessed or specific actions can be performed. This can help to: • Limit access to critical systems after hours. • Prevent unauthorized activities during particular periods. • Reduce the attack surface available to potential threats.

Transition Best Practices

Organizations should follow strict guidelines when an employee transitions from or into a new position. Creeping privileges occur when a user's job position changes, and the user is granted a new set of access privileges. Still, the user's current access privileges are not removed or modified, resulting in privilege escalation. As a result, the user accumulates unnecessary privileges for the current work tasks. The principle of least privilege and separation of duties are

countermeasures against creeping privileges. To avoid creeping privileges and to best protect the security of information, the following precautions should be taken in each stage of the account's life cycle:

Event	Precautions
Account creation	When creating an account, apply the appropriate access rights based on the job role implemented in the access control system. Use the principle of least privilege and grant only the minimum privileges required to perform the position's duties.
Active accounts	During the life of an account: • Modify access rights as job roles and circumstances change. • Monitor password resets and lockouts to ensure account security. • Re-evaluate access rights periodically.
Old accounts	When an account is no longer needed, take appropriate actions to: • Delete accounts that will no longer be used. • Rename accounts to give new users in the same job role the same access privileges. • Lock accounts that will not be used for extended periods to prevent them from being used. • Remove unnecessary rights from accounts that will be kept on the system. • Archive important data or files the user owns or assign ownership to another user. • Prohibit generic user accounts, such as the Guest or Administrator users, on Windows systems. • End-of-life procedures should include deactivating or deleting unused accounts and destroying data that might remain on storage media. This will prevent sensitive data from being accessible to unauthorized users.

4.1.4 Access Control Models (Lesson Video)

Transcript:

Depending on your organization's needs, there are several ways to implement access control. In this lesson, we'll look at some common implementation models.

Let's start with the least restrictive model, Discretionary Access Control, or DAC. With DAC, every resource has an owner. That owner decides who has access to the resource. DAC uses programs like access control lists, or ACLs. A good example is NTFS within a Windows system.
Each NTFS file and folder has an owner. The owner can go into the file or folder's access control list and decide which user or group can access the resource. Because access is resource-specific, a lot of administrative work is required to implement and maintain these policies on each individual resource.
Mandatory access control, or MAC, is a static system with classification labels and levels. When you're using MAC, every computer, every file, and every object is assigned a label. These labels indicate how important the object is. Each user is assigned an access level. MAC compares the object labels with the user's level to grant or deny access to a given resource.
Let's say your organization uses three labels: Confidential, Secret, and Top Secret. Your organization also uses three user access levels. Users with access level 1 can see anything labeled Confidential. They cannot see anything labeled

Secret or Top Secret. Users with access level 2 can see anything labeled Confidential or Secret, but cannot see anything labeled Top Secret. Users with access level 3 can see anything labeled Confidential, Secret, or Top Secret.
It's important to note that permissions can't be altered for specific instances. For example, the data owner can't prevent specific people with level 2 clearance from accessing certain documents labeled as level 1. It's an all-or-none deal.
Next, we have role-based access control. This model is a hybrid between MAC and DAC, and it's probably the most commonly used. Role-based access control means that your role within the organization determines whether or not you're able to access certain kinds of data.
For example, Mary is the CFO, so she needs full access to important company financial records, while Aubrey is the receptionist and will only need to see calendar information for everyone in the organization.
We also have rule-based access controlâ€""don't confuse it with role-based! Rule-based access control is used with routers through router access control lists. With a router access control list, or ACL, you decide which IPs are allowed through the router using rules. Either you match that rule, or you don't. This has nothing to do with your user account, what group you're a member of, or even a classification label. The only thing that matters is whether the condition meets the rules configured on the router.
Attribute-Based Access Control, or ABAC, provides more flexibility because it combines object attributes to determine access. These attributes can be a number of different things, such as a user's role, position, or even project association. ABAC rules use an if-then-else format. If the user has the required attribute, they're granted access. If the user doesn't have the required attribute, they're denied access.
For example, let's say we have a user named RBradbury. This user's role is manager. Their department is development, and they're currently working on a project called AmazingApp.
Now, let's say RBradbury wants to access a file on the server. This file has been configured with several attributes: role = manager, department = development, and project = BoringApp.
When RBradbury tries to access the file, the system asks, "Are you a manager?" Yes. "Is your department development?" Yes. "Are you on the BoringApp project?" No. Since it hit a false return, the user is denied access to the file.
Modern security concerns extend beyond a desktop in the office. Conditional Access is a way to enforce access control while also encouraging users to be productive wherever they are. Conditional access isn't intended to be the first point of security. Instead, it steps in after first-factor authentication has been granted. Conditional access can be configured to consider many different factors.
Administrators can maintain specific control at the user or group level. They can permit or deny access based on an IP address or an IP range. Administrators can also use specific applications or devices to permit, restrict, or deny access to users.
That's it for this lesson. In this video, we discussed several access control models: discretionary access control, mandatory access control, role-based access control, rule-based access control, attribute-based access control, and conditional access control.

4.1.5 Access Control Model Facts

Authorization is the part of identity and access management that assigns privileges to network users and services. Implementing an access control model helps an organization manage the implications of privilege assignments and accounts for the actions of both regular and privileged administrative users. Account policies help you to protect credentials and to detect and manage risks from compromised accounts.

This lesson covers the following topics:

- Discretionary and mandatory access control
- Role- and attribute-based access control
- Rule-based access control
- Least privilege permission assignments
- Account attributes and access policies
- Location-based policies
- Time-Based Restrictions

Discretionary and Mandatory Access Control

A user account that has been authenticated can be allocated rights and permissions on networks, computers, and data. An access control model describes the principles that govern how users receive rights.

Discretionary Access Control

Discretionary access control (DAC) is based on the primacy of the resource owner. In a DAC model, every resource has an owner. The owner creates a file or service, although ownership can be assigned to another user. The owner has full control over the resource, and they can modify its access control list (ACL) to grant rights to others.

DAC is the most flexible model and is currently implemented widely in computer and network security. In file system security, it is the model used by default for most UNIX/Linux distributions and Microsoft Windows. As the most flexible model, it is also the weakest because it makes centralized administration of security policies the most difficult to enforce. It is also the easiest to compromise, as it is vulnerable to insider threats and abuse of compromised accounts.

Mandatory Access Control

The DAC model exposes information to the threat of compromise via the privileged owner accounts. Mandatory access control (MAC) is based on security clearance levels. Rather than defining ACLs on resources, each object is given a classification label, and each subject is granted a clearance level. In a confidentiality-oriented multilevel system, subjects are permitted to read objects classified at their own clearance level or below. For example, a user with Top-Secret clearance could read data with Top-Secret, Secret, and Confidential classification labels. A user with Secret clearance could access Secret and Confidential levels only.

Labeling objects and granting clearance takes place using pre-established rules. The critical point is that these rules are nondiscretionary and cannot be changed by any subject account.

As a simple classification system is inflexible, most MAC models add the concept of compartment-based access. For example, a data file might be at Secret classification and located in the HR compartment. Only subjects with Secret and HR clearance could access the file.

In MAC, users with high clearance are not permitted to write low-clearance documents. This is referred to as write up, read down. This prevents, for example, a user with Top Secret clearance from republishing some Top Secret data that they can access with Secret clearance.

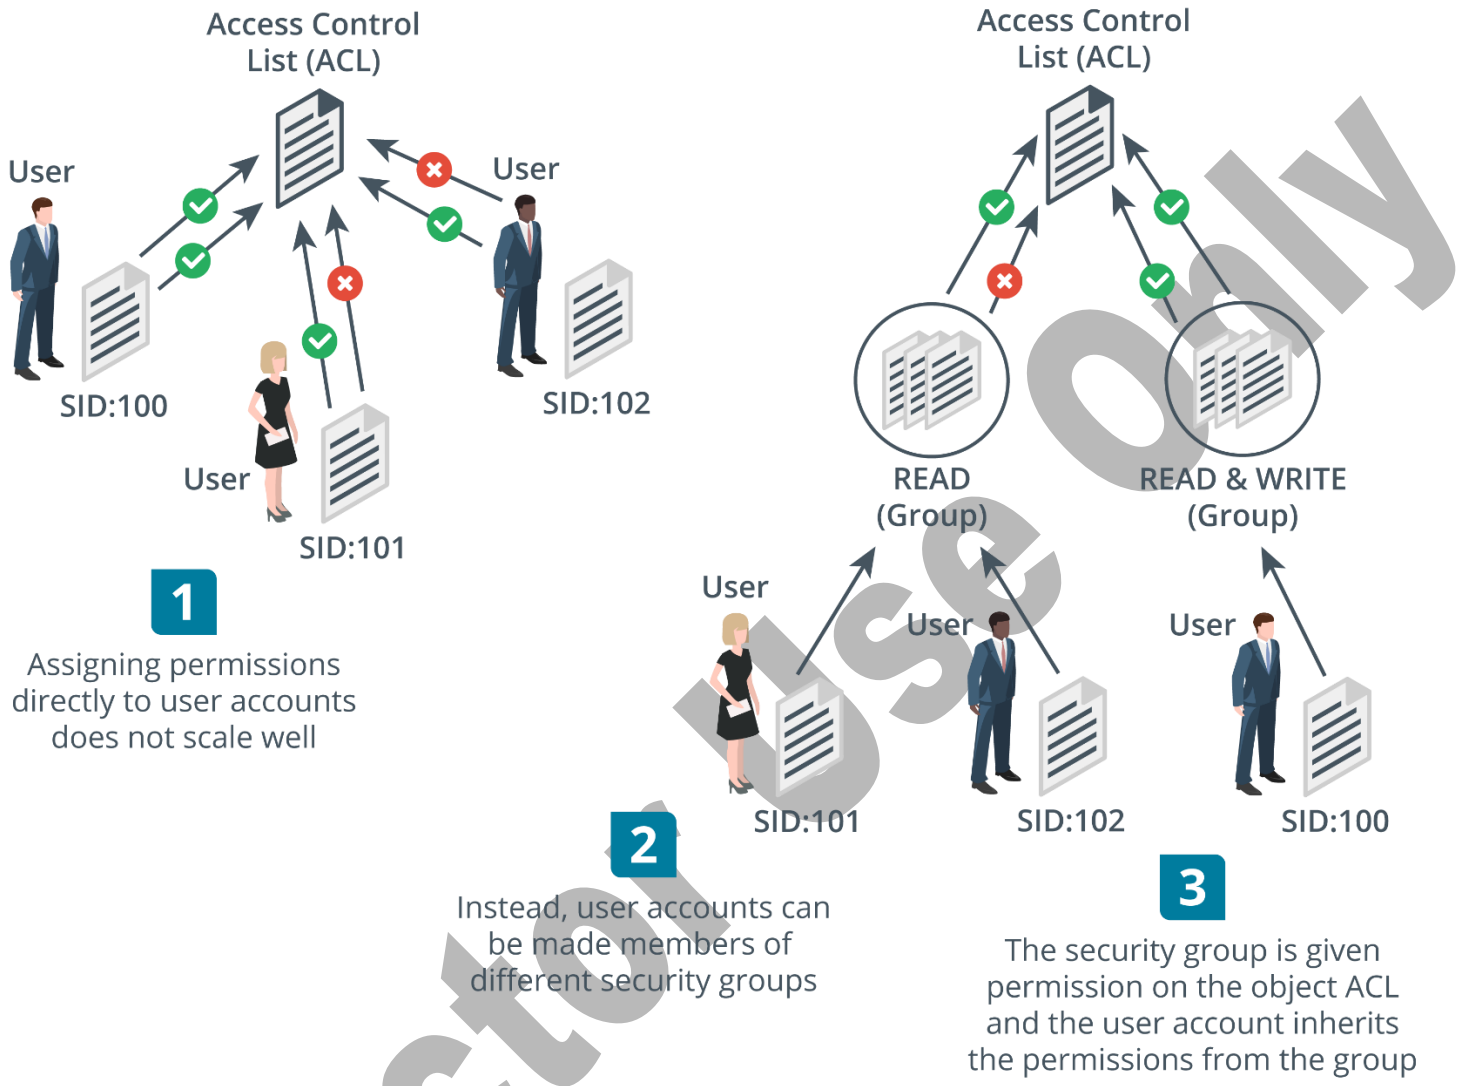
Role- and Attribute-Based Access Control

Role- and attribute-based access control use nondiscretionary, rules-based permissions assignments with more flexibility than MAC.

Role-Based Access Control

Role-based access control (RBAC) means that an organization defines its permission requirements in terms of the tasks that an employee or service must be able to perform. Each set of permissions is a role. Each principal (user or service account) is allocated to one or more roles. Under this system, the right to modify the permissions assigned to each role is reserved to a system owner. Therefore, the system is nondiscretionary as each principal cannot modify the ACL of a resource, even though they can change the resource in other ways. Principals gain rights implicitly (through being assigned to a role) rather than explicitly (being assigned the right directly).

The concept of a security group account goes some way toward turning a discretionary system into a role-based one. Rather than assigning rights directly to user accounts, the system owner assigns user accounts to security group accounts. Principals gain rights by being made a member of a security group. A principal can be a member of multiple groups and, therefore, receive rights and permissions from several sources.



Using security groups to assign privileges. (Images © 123RF.com.)

RBAC can be partially implemented by mapping security groups onto roles, but they are not identical schemes. Membership in security groups is largely discretionary (assigned by administrators rather than determined by the system). Also, ideally, a principal should only inherit the permissions of a role to complete a particular task rather than retain them permanently. Administrators should be prevented from escalating their own privileges by assigning roles to their own accounts arbitrarily or boosting a role's permissions.

Attribute-Based Access Control

Attribute-based access control (ABAC) is the most fine-grained type of access control model. As the name suggests, an ABAC system makes access decisions based on a combination of subject and object attributes plus any context-sensitive or system-wide attributes. As well as group/role memberships, these attributes could include information about the OS currently being used, the IP address, or the presence of up-to-date patches and antimalware. An attribute-based system monitors the number of events or alerts associated with a user account or with a resource or tracks access requests to ensure they are consistent in terms of timing or geographic location. It can be programmed to implement policies such as M-of-N control and separation of duties.

The attributes assigned to a resource constitute a policy that uses Boolean logic to determine who can access the resource. An example of a file access policy might include the following attributes: role = manager, department = development, and project = NewApp. Only users who possess all three attributes can access the file.

Rule-Based Access Control

Rule-based access control refers to any sort of access control model where access control policies are determined by system-enforced rules rather than system users. As such, RBAC, ABAC, and MAC are all examples of rule-based (or nondiscretionary) access control.

Conditional access is an example of rule-based access control. A conditional access system monitors account or device behavior throughout a session. If certain conditions are met, it may suspend the account or require the user to reauthenticate, perhaps using a two-step verification method.

Conditional access is a way to enforce access control while encouraging users to be productive wherever they are. Conditional access isn't intended to be the first point of security. Instead, it steps in after the first-factor authentication has been granted. Conditional access policies ask a user to complete an action to access a resource. Depending on the level of security of the requested resource, the user may be required to complete more actions. For policy decisions, conditional access can be configured to consider many different factors, including:

- Implement control at the user or group level.
- Permit or deny access based on an IP address or an IP range.
- Permit or deny access to users who are using specific applications.
- Permit, restrict, or deny access to users using specific devices or device states.

The User Account Control (UAC) and sudo restrictions on privileged accounts are examples of conditional access. The user is prompted for confirmation or authentication when making requests that require elevated privileges. Role-based rights management and ABAC systems can apply a number of criteria to conditional access, including location-based policies.

An example of a rule-based access control implementation is a router access control list that allows or denies traffic based on characteristics within the packet, such as IP address or port number. Because rule-based access control does not consider the subject's identity, a system that uses rules can be regarded as mandatory access control.

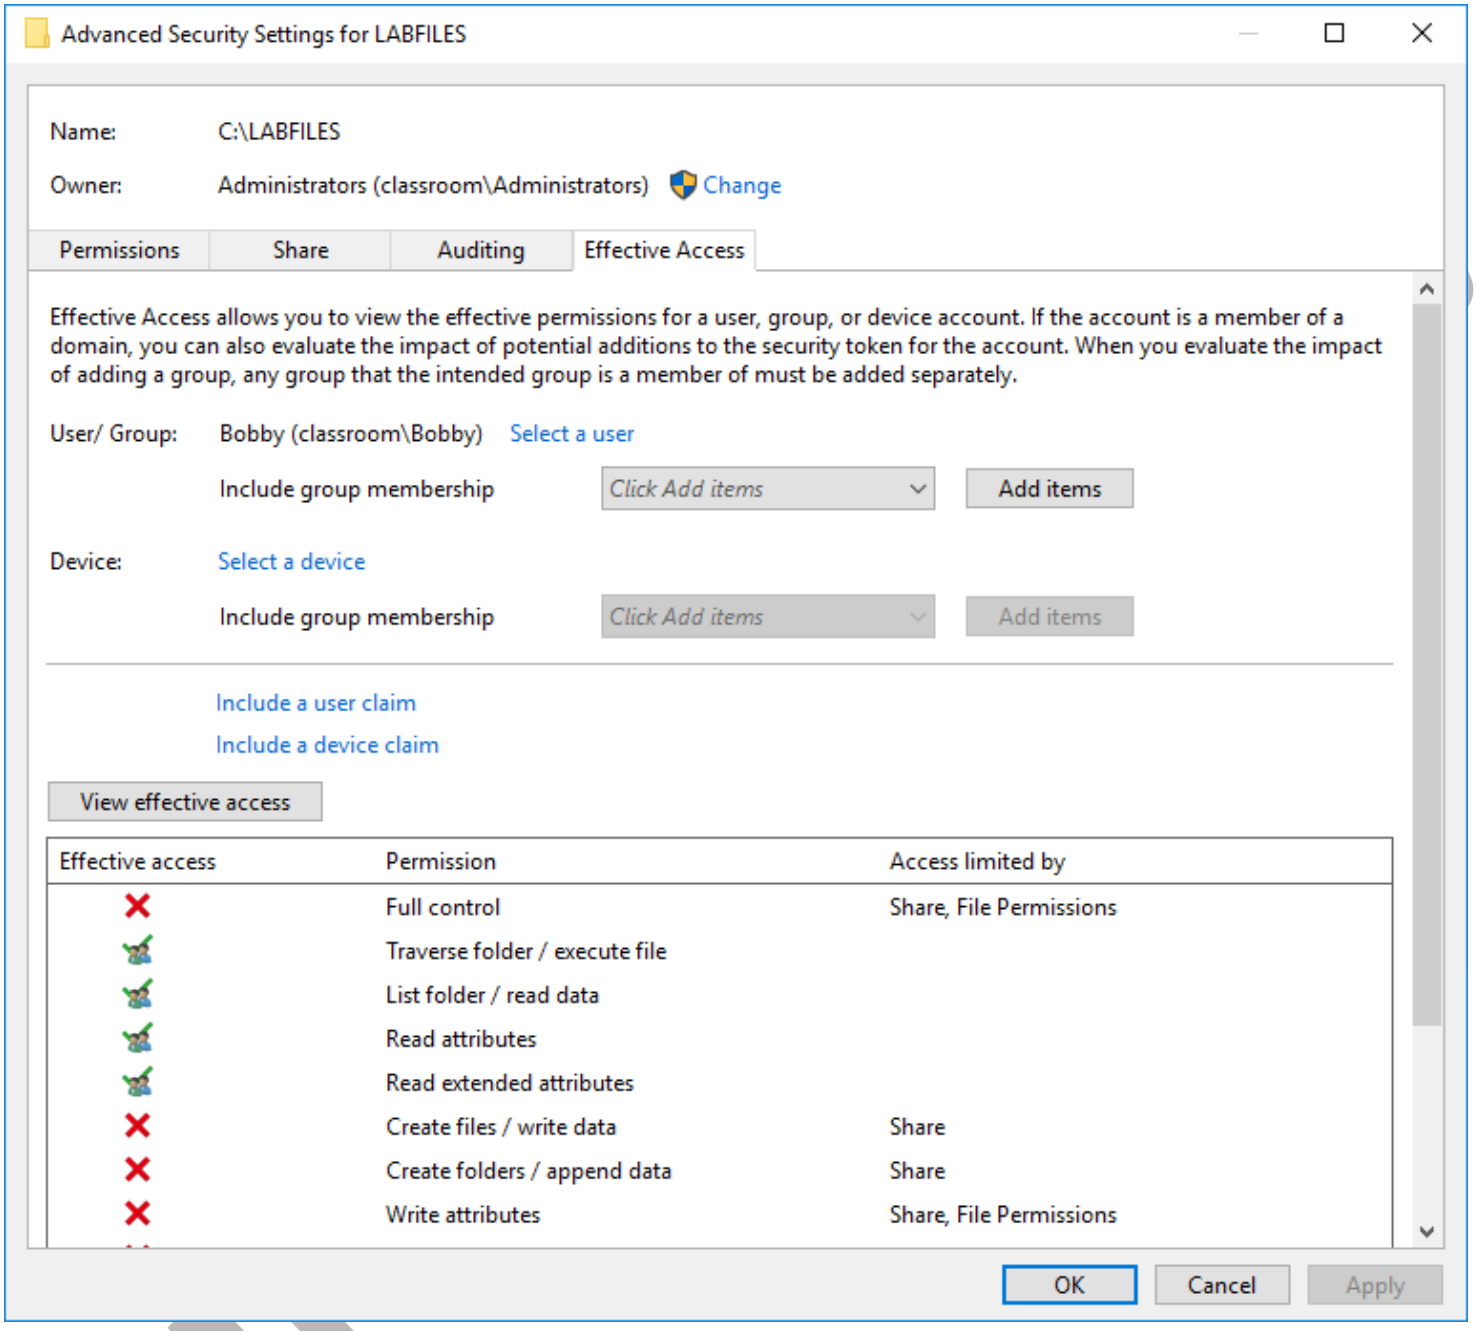
Least Privilege Permission Assignments

Least privilege means that a principal is granted the minimum possible sufficient rights to complete a task they are authorized to perform. This mitigates risk if an account should be compromised and fall under the control of a threat actor. Least privilege involves a design phase, where analysis of business workflows determines what roles and permissions are required.

While least privilege is a strong design principle, successfully implementing it can be challenging. Where many users, groups, roles, and resources are involved, managing permission assignments and implications is complex and time-consuming. Improperly configured accounts can have two different impacts. On the one hand, setting privileges that are too restrictive creates a large volume of support calls and reduces productivity. On the other hand, granting too many privileges to users weakens the system's security and increases the risk of malware infection and a data breach.

Ensuring least privilege also involves continual monitoring to prevent authorization creep. Authorization creep refers to a situation where a user acquires more rights, either directly or by being added to security groups or roles.

For example, a user may be granted elevated privileges temporarily. In this case, a system is needed to ensure that the privileges are revoked at the end of the agreed period. A system of auditing should regularly review privileges, monitor group membership, review access control lists for each resource, and identify and disable unnecessary accounts.



Determining effective permissions for a shared folder. (Screenshot used with permission from Microsoft.)

Provisioning is the process of setting up a service according to a standard procedure or best practice checklist. The IT department must keep track of all assets under management, and user accounts are a type of asset. User accounts are provisioned for new employees and temporary access, such as by consultants and contractors. Some businesses may also need to set up customer accounts.

Provisioning a user account involves the following general steps:

- **Identity proofing** — verifies that the person is who they say they are by checking official documents and records. Circumstances might also demand a background check, which verifies current and previous

addresses, education, or previous employment and whether the person has a criminal record or credit issues.

- **Issuing credentials** — allows the user to select a password known only to them and enroll them with biometric or token-based authenticators.
- **Issuing hardware and software assets** — the user will typically need a computer and smartphone and possibly local copies of licensed software apps. Employees need sufficient resources to do their job. If their resources are inadequate, they might try to obtain hardware and software directly (shadow IT).
- **Teaching policy awareness** — by scheduling training and providing access to learning resources so that the employee or contractor is aware of security policies and risks. They must also be aware of policies for the personal use of any IT assets issued to them.
- **Creating permissions assignment** — by identifying the work roles that the account must support and configuring the appropriate rights using a role-based, mandatory, or attribute-based access control model. If the account is granted privileged access, it should be tagged for close monitoring.

Deprovisioning is the process of removing the access rights and permissions allocated to an employee when they leave the company or from a contractor when a project finishes. This involves removing the account from any roles or security groups. The account might be disabled for a period and then deleted or deleted immediately.

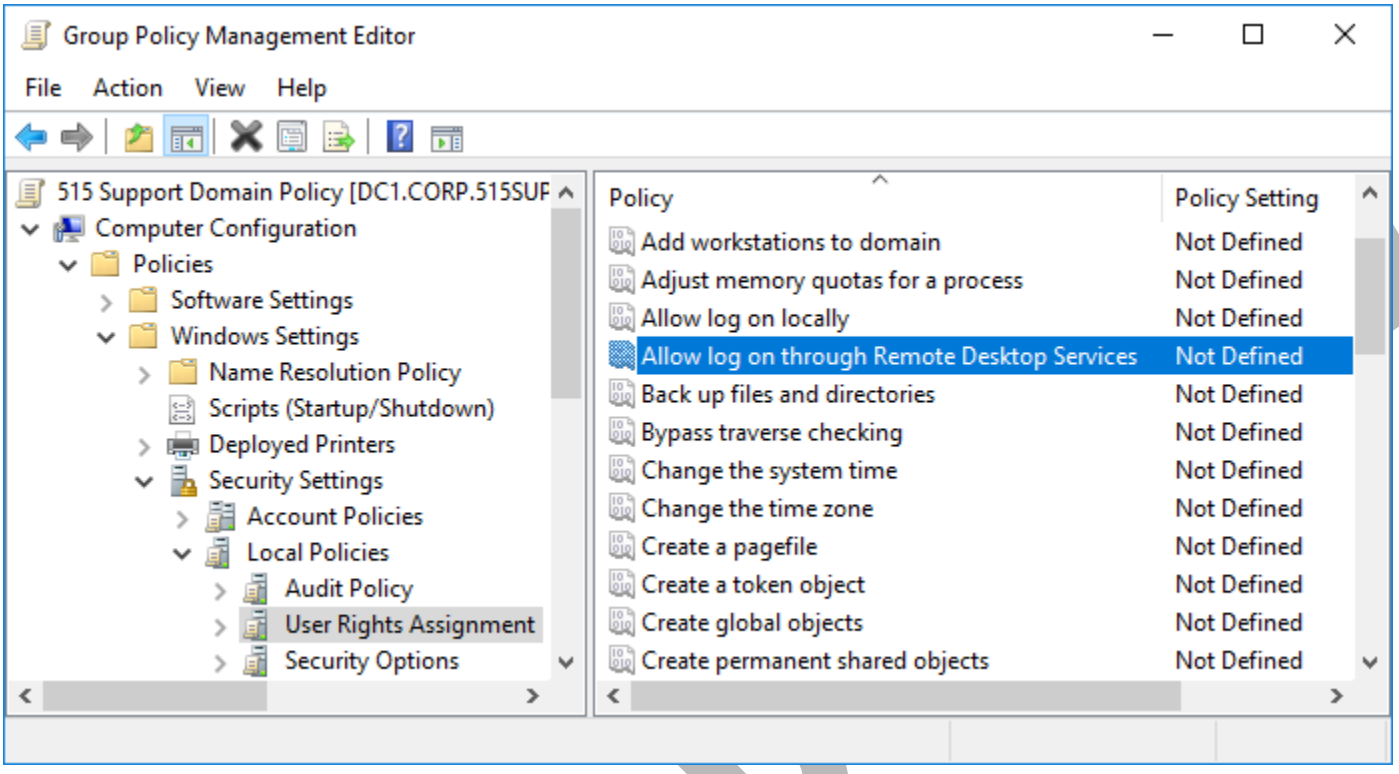
Account Attributes and Access Policies

A user account is defined by a unique security identifier (SID) , a name, and a credential. Each account is associated with a profile. The profile can be defined with custom identity attributes describing the user, such as a full name, email address, contact number, department, etc. The profile may support media such as an account picture.

As well as attributes, the profile will usually provide a location for storing user-generated data files (a home folder). The profile can also store per-account settings for software applications.

Each account can be assigned permissions over files and other network resources and access policies or privileges over the use and configuration of network hosts. These permissions might be assigned directly to the account or inherited through membership in a security group or role. Access policies determine things like the right to log on to a computer locally or via a remote desktop, install software, change the network configuration, etc.

On a Windows Active Directory network, access policies can be configured via group policy objects (GPOs) . GPOs can be used to configure access rights for user/group/role accounts. GPOs can be linked to network administrative boundaries in Active Directory, such as sites, domains, and organizational units (OU).



Configuring access policies and rights using Group Policy Objects in Windows Server 2016. (Screenshot used with permission from Microsoft.)

Policy-based restrictions can be used to mitigate some risks of account compromise through the theft of credentials.

Location-Based Policies

A user or device can have a logical network location identified by an IP address, subnet, virtual LAN (VLAN), or organizational unit (OU). This can be used as an account restriction mechanism. For example, a user account may be prevented from logging on locally to servers within a restricted OU.

The geographical location of a user or device can be calculated using a geolocation mechanism:

- **IP address** — can be associated with a map location to varying degrees of accuracy based on information published by the registrant, including name, country, region, and city. The registrant is usually the Internet service provider (ISP), so the information you receive will provide an approximate location of a host based on the ISP. If the ISP is one that serves a large or diverse geographical area, it is more difficult to pinpoint the location of the host Internet service providers (ISPs). Software libraries, such as GeoIP, facilitate querying this data.
- **Location services** — are methods used by the OS to calculate the device's geographical position. A device with a global positioning system (GPS) sensor can report a highly accurate location when outdoors. Location services can also triangulate to cell towers, Wi-Fi hotspots, and Bluetooth signals where GPS is not supported.

Time-Based Restrictions

There are four main types of time-based policies:

- A **time-of-day restrictions policy** establishes authorized login hours for an account.
- A **duration-based login policy** establishes the maximum time an account may be logged in for.
- An **impossible travel time/risky login policy** tracks the location of login events over time. If these do not meet a threshold, the account will be disabled. For example, a user logs in to an account from a device in New York City. A couple of hours later, a login attempt is made from Los Angeles but is refused, and an alert is raised because it is not feasible for the user to be in both locations.
- A **temporary permissions policy** removes an account from a security role or group after a defined period.

4.1.6 Practice Questions (Section Quiz)

q_acc_ctrl_aaa_secp8

An organization's IT department wants to implement a security model responsible for verifying user identities, determining access rights, and monitoring activities within a system.

Which concept is MOST appropriate for the department to implement?

Answers:

- ***AAA**
- Zero trust
- RBAC
- Policy engine

Explanation:

Authentication, authorization, and accounting (AAA) verifies a user's identity (authentication), determines what resources the user can access (authorization), and monitors the user's activities within the system (accounting).

Zero trust might involve elements of AAA, but does not encompass all the aspects of the AAA model.

Role-based access control (RBAC) is the role assigned to individual users within an enterprise. RBAC primarily involves authorization and does not inherently provide all the functionalities of AAA.

The policy engine makeup includes subject and host identities and credentials, access control policies, up-to-date threat intelligence, behavioral analytics, and other results of host and network security scanning and monitoring.

q_acc_ctrl_access_control_01_secp8

The information technology department in a large organization is implementing a new system where the system allows, determines, and enforces various resources based on predefined company guidelines.

Which concept is the department implementing?

Answers:

- ***Policy-driven access control**
- Authorization models
- AAA
- Zero trust

Explanation:

Policy-driven access control uses policies to control access to resources, allowing the organization to systematically enforce rules about who can access which resources under which conditions.

Authorization models are more generic methods for determining what resources a user or system can access within a system. While crucial to any secure system, they do not necessarily incorporate company policies for controlling access.

Authentication, authorization, and accounting (AAA) includes policy enforcement elements in its scope. However, AAA is a broader concept that also involves verifying the user's identity (authentication) and tracking their activities (accounting).

Zero trust does not focus on enforcing company policies to control access, but verifies everything trying to connect to the system.

q_acc_ctrl_access_control_02_secp8

A corporation's IT department is integrating a new framework that permits, ascertains, and applies various resources in accordance with established company policies.

Which principle should the department incorporate?

Answers:

- ***Policy-driven access control**
- Authorization models
- AAA
- Zero trust

Explanation:

Policy-driven access control uses policies to control access to resources, allowing the organization to systematically enforce rules about who can access which resources under which conditions.

Authorization models are more generic methods for determining what resources a user or system can access within a system. While crucial to any secure system, they do not necessarily incorporate company policies for controlling access.

Authentication, authorization, and accounting (AAA) includes policy enforcement elements in its scope. However, AAA is a broader concept that also involves verifying the user's identity (authentication) and tracking their activities (accounting).

Zero trust does not focus on enforcing company policies to control access, but verifies everything trying to connect to the system.

q_acc_ctrl_authentication_secp8

Which of the following is the term for the process of validating a subject's identity?

Answers:

- ***Authentication**
- Identification
- Authorization
- Auditing

Explanation:

Authentication is the process of validating a subject's identity. Authentication includes the identification process, the providing of input by the user to prove his or her identity, and the acceptance of that input as valid by the system.

Authorization grants or denies a subject's access to an object based on the level of permissions or the actions allowed on the object.

Identification identifies the subject. Examples include a username or a user ID number.

Auditing maintains a record of a subject's activity within the information system.

q_acc_ctrl_cia_triad_secp8

What principle of an organization's information security system ensures that only authorized individuals can access sensitive data, the data remains unaltered during storage and transfer, and the data is always accessible when needed?

Answers:

- ***CIA triad**
- Authenticating people
- Access control list
- Two-factor authentication

Explanation:

The CIA (confidentiality, integrity, and availability) triad is critical to information security. Confidentiality ensures that data is accessible only to authorized personnel. Integrity ensures that data remains unaltered during storage and transfer. Availability guarantees that the data is always accessible.

Authenticating people contributes to the confidentiality aspect of the CIA triad by allowing only verified users to access data, but does not cover integrity and availability.

An access control list (ACL) is a rule set that controls network traffic and reduces network attacks. ACL contributes to confidentiality, but does not assure the integrity and availability of data.

Two-factor authentication adds an extra layer of security by requiring a second factor for verification. This does not cover all aspects of the CIA triad.

q_acc_ctrl_gap_analysis_01_secp8

After implementing the National Institute of Standards and Technology (NIST) Cybersecurity Framework, the chief information security officer (CISO) is assessing the company's security posture to identify deficiencies from the framework's recommendations.

What process can the CISO run to get a better sense of what the company needs to improve upon?

Answers:

- Implement business continuity plan
- Penetration test
- Implement disaster recovery plan
- ***Gap analysis**

Explanation:

The CISO would be preparing a gap analysis report. This report shows the defects in the company's current security posture against the NIST Cybersecurity Framework (or any other baseline security framework).

A business continuity plan would significantly improve security posture, but the CISO is verifying what currently exists, not what should exist.

The CISO would not be performing a penetration test. However, this task may show up as a remediation step during a gap analysis report.

Like penetration testing, a disaster recovery plan would likely be a remediation step for any defects the CISO finds during the analysis.

q_acc_ctrl_gap_analysis_02_secp8

The IT department of a corporation evaluates its security mechanisms to identify areas lacking sufficient protection.

Which of the following techniques should the IT department employ?

Answers:

- ***Gap analysis**
- Zero trust
- Authorization models
- Non-repudiation

Explanation:

Gap analysis assesses the differences in performance between a company's information systems or software applications to determine whether they meet requirements. If requirements aren't met, the analysis helps determine what steps to take to meet them.

Zero trust is a strategy that assumes no user or device is trustworthy, whether located inside or outside the network, but does not specifically aim to identify deficiencies in security.

Authorization models dictate what resources a user or system can access within a system. They are not tools used to assess security gaps.

Non-repudiation assures the origin and integrity of transmitted data, preventing entities from denying the validity of the data. However, this is not a technique to identify areas lacking sufficient protection.

q_acc_ctrl_gap_analysis_03_secp8

An IT department is using a technique to assess the differences in performance between their systems, looking to see if the systems meet the established requirements.

Which of the following terms BEST describes the technique the IT department is using?

Answers:

- ***Gap analysis**

- Zero trust
- Authorization models
- Non-repudiation

Explanation:

Gap analysis assesses the differences in performance between a company's information systems or software applications to determine whether they meet requirements. If requirements aren't met, the analysis helps determine what steps to take to meet them.

Zero trust is a strategy that assumes no user or device is trustworthy, whether located inside or outside the network, but does not specifically aim to identify deficiencies in security.

Authorization models dictate what resources a user or system can access within a system. They are not tools used to assess security gaps.

Non-repudiation assures the origin and integrity of transmitted data, preventing entities from denying the validity of the data. However, this is not a technique to identify areas lacking sufficient protection.

q_acc_ctrl_iam_process_secp8

You are the head of the IT department at a large corporation. Recently, there have been several security breaches, and you suspect that these breaches are due to issues with your Identity and Access Management (IAM) processes. You decide to conduct a thorough review of your IAM processes.

Which of the following steps should you prioritize and why?

Answers:

- Reviewing the identification process to ensure that each user, device, or process on the network is uniquely represented.
- Checking the authentication process to verify that each subject is who or what it claims to be when attempting to access a resource.
- ***Assessing the authorization process to determine what rights subjects should have on each resource and whether those rights are being enforced.**
- Examining the accounting process to track authorized usage of a resource or use of rights by a subject and alert when unauthorized use is detected or attempted.

Explanation:

Assessing the authorization process should be the priority. This process determines what rights subjects should have on each resource and whether those rights are being enforced. If this process is flawed, subjects may gain access to resources they should not have access to, leading to security breaches.

Reviewing the identification process is important, but not the first step to take when dealing with security breaches. Identification only ensures that each user, device, or process on the network is uniquely represented, but does not prevent unauthorized access if the authentication and authorization processes are flawed.

Checking the authentication process is crucial, verifying that each subject is who or what it claims to be when attempting to access a resource. However, even if the authentication process is robust, breaches can still occur if the authorization process is flawed and allows subjects to access resources they should not have access to.

Examining the accounting process is important for detecting and alerting when unauthorized use is detected or attempted. However, this process is reactive rather than proactive, helping identify when a breach has occurred, but not preventing breaches from happening in the first place. Therefore, while important, examining the accounting process should not be the first step in addressing security breaches.

q_acc_ctrl_iam_secp8

What is the purpose of identity and access management (IAM) automation in the onboarding process for new employees in an organization?

Answers:

- ***To automate the provisioning and access management tasks associated with new employees.**
- To facilitate knowledge sharing and continuity as employees move into new roles.
- To establish the rules for the acceptable ways in which network and computer systems may be used by defining acceptable behavior by users.
- To carefully plan and assess the implementation of changes in the IT system.

Explanation:

Automating IAM streamlines onboarding, assigns access based on roles and policies, and syncs data with HR systems. This process boosts efficiency, consistency, and security, benefiting organizations in many ways.

Playbooks promote knowledge exchange, consistency, and effectiveness. They guide personnel to maintain operational standards and support transition.

The acceptable use policy (AUP) outlines the appropriate ways to use network and computer systems. It defines acceptable behavior for users.

Assessing and planning changes in an IT system involves a careful evaluation of their impact on related components. However, this process is separate from automating IAM onboarding for new employees.

q_acc_ctrl_nist_framework_secp8

In the context of the NIST Cybersecurity Framework, which function involves identifying, analyzing, containing, and eradicating threats to systems and data security?

Answers:

- Identify
- Protect
- ***Respond**
- Recover

Explanation:

Respond is the correct answer. The Respond function involves taking action regarding a detected cybersecurity incident. The goal is to contain the impact of a potential cybersecurity event.

Identify involves developing an understanding to manage cybersecurity risk to systems, people, assets, data, and capabilities. Identify does not directly involve the process of identifying, analyzing, containing, and eradicating threats.

Protect involves developing and implementing appropriate safeguards to ensure delivery of critical services. Protect is more about prevention than response.

Recover involves maintaining plans for resilience and to restore any capabilities or services that were impaired due to a cybersecurity incident. Recover is more about restoration and recovery after an incident has occurred.

q_acc_ctrl_non_repudiation_01_secp8

When sending confidential data over a network, a company wants to ensure both parties involved cannot deny the validity of the transmitted data.

Which security principle should they prioritize?

Answers:

- ***Non-repudiation**
- Authentication, authorization, and accounting (AAA)
- Adaptive identity
- Zero trust

Explanation:

Non-repudiation is crucial for verifying that transmitted data originated from a verified sender and reached the intended recipient, and neither party can deny the authenticity of the data.

Authentication, authorization, and accounting (AAA) is essential for overall network security but does not provide a specific non-repudiation feature.

Adaptive identity primarily relates to systems that dynamically adjust user access rights based on behavior or other contextual factors. While important for maintaining security, adaptive identity does not directly address non-repudiation.

Zero trust is a security concept centered on the belief that organizations should not automatically trust anything inside or outside their perimeters and instead must verify everything trying to connect to their systems. However, zero trust does not ensure non-repudiation by itself.

q_acc_ctrl_non_repudiation_02_secp8

A company transmits data across a network, ensuring the non-repudiation security principle.

What is the key benefit this provides to both the sender and the recipient of the data?

Answers:

- ***Neither party can deny the authenticity of the data.**
- Both parties can adapt their identity dynamically.
- Both parties should not trust anything inside or outside the network.
- Both parties have control over authentication, authorization, and accounting.

Explanation:

Non-repudiation is a security principle that ensures data originated from a verified sender and reached the intended recipient. This process means neither party can deny the authenticity of the data.

Adaptive identity is a part of advanced access control models but does not directly provide the certainty of data origin and receipt that non-repudiation does.

Not trusting anything inside or outside the network is a zero-trust policy, but does not provide non-repudiation.

While authentication, authorization, and accounting (AAA) is a key security framework used to control user access and track user activity in an organization's network, but does not inherently provide non-repudiation.

q_acc_ctrl_policy_point_secp8

A security analyst wants to ensure that the privileges granted to an individual align with the role within the organization.

What is the primary tool that the analyst should implement?

Answers:

- ***Policy enforcement point**
- Non-repudiation
- Authenticating systems
- Zero trust

Explanation:

Policy enforcement points enforce decisions about whether to grant access to a requested resource or not. Policy enforcement is instrumental in enforcing authorization models.

Non-repudiation ensures that a party to a transaction or communication cannot refute their involvement. However, non-repudiation does not help in aligning individual privileges with roles in an organization.

Authenticating systems does not help specifically with matching privileges to roles, which is the focus of authorization models.

Zero trust is a security concept that recommends not trusting any entity inside or outside the organization by default. Zero trust does not assist in granting access based on roles.

q_acc_ctrl_zero_trust_planes_secp8

You are a cybersecurity expert implementing a zero trust model in a large organization. You are tasked with designing the control and data planes.

Which of the following strategies should you prioritize and why?

Answers:

- Focus on the control plane to ensure that all network devices are properly configured and managed.
- Prioritize the data plane to ensure that data traffic flows securely and efficiently across the network.
- ***Balance your focus between the control and data planes, ensuring both are optimized for security and efficiency.**
- Neither, focus on the application plane to ensure that applications are secure and function properly.

Explanation:

Balancing your focus between the control and data planes is the most effective strategy. In a zero trust model, both planes play crucial roles. The control plane ensures proper network configuration and management, while the data plane handles data traffic. Ensuring both are optimized for security and efficiency can prevent breaches and ensure smooth network operations.

Focusing on the control plane is important as it is responsible for network management and configuration. However, focusing solely on the control plane may leave the data plane, which handles the actual data traffic, vulnerable to attacks. Therefore, while the control plane is crucial, it should not be the only focus.

Prioritizing the data plane is crucial as it handles the actual data traffic across the network. Ensuring the security and efficiency of the data plane can prevent data breaches and ensure smooth network operations. However, without a properly configured control plane, the data plane may not function optimally.

While the application plane is important, it is not the primary focus when designing control and data planes in a zero trust model. The application plane deals with how applications are delivered to end-users and does not directly impact the configuration or security of the control and data planes. Therefore, while it should not be neglected, it should not be the primary focus in this scenario.

q_acc_ctrl_zero_trust_secp8

A network administrator for a technology company is introducing a new cybersecurity model to limit data breaches. They wish to enforce a strategy where every system or user inside or outside the network perimeter must prove their legitimacy before accessing resources.

What principle would be MOST effective in implementing their new strategy?

Answers:

- ***Zero trust**
- Adaptive identity
- Role-based access control
- Policy-driven access control

Explanation:

Zero trust verifies the authenticity of every system or user trying to connect to its resources, serving as the best strategy in this scenario.

Adaptive identity involves systems dynamically adjusting user access rights based on behavior or context rather than requiring every system or user to prove their legitimacy.

Role-based access control (RBAC) does not necessitate the verification of every system or user, which is the central idea of zero trust.

Policy-driven access control does offer a layer of security by determining who to allow access to specific network resources. But policy-driven access control does not incorporate the verify-everything concept of zero trust.

q_acct_bstpract_least_01_secp8

You assign access permissions so that users can only access the resources required to accomplish their specific work tasks.

Which security principle are you complying with?

Answers:

- Job rotation
- ***Principle of least privilege**
- Cross-training
- Need to know

Explanation:

The principle of least privilege is the assignment of access permissions so that users can only access the resources required to accomplish their specific work tasks.

Job rotation and cross-training involve training groups of employees how to perform multiple job roles and periodically rotating those roles. Need to know is a feature of MAC environments where data within your classification level is compartmentalized and requires specific work-task needs for privilege access.

q_acct_bstpract_least_02_secp8

An access control list (ACL) contains a list of users and allowed permissions.

What is it called if the ACL automatically prevents access to anyone who is not on the list?

Answers:

- ***Implicit deny**
- Explicit deny
- Implicit allow
- Explicit allow

Explanation:

With implicit deny, users or groups that are not specifically given access to a resource are denied access. Implicit deny means that there is an assumed or unstated deny that prevents access to anyone not explicitly on the list.

Explicit deny identifies users or objects that are not granted access.

Explicit allow specifically identifies the objects that are allowed access.

Implicit allow is a policy that allows access unless it is explicitly denied. (This ACL type is rarely used.)

q_acct_bstpract_least_03_secp8

You want to implement an access control list in which only the users you specifically authorize have access to the resource. Anyone not on the list should be prevented from having access.

Which of the following methods of access control should the access list use?

Answers:

- ***Explicit allow, implicit deny**
- Explicit allow, explicit deny
- Implicit allow, implicit deny

- Implicit allow, explicit deny

Explanation:

The access list should use explicit allow--users who are allowed access are specifically identified. The access list should also use implicit deny--users who are not explicitly allowed access are denied access.

Explicit deny identifies users or objects that are denied access.

Implicit allow allows access unless it is explicitly denied. This type of ACL is rarely implemented.

q_acct_bstpract_need_secp8

Which of the following principles is implemented in a mandatory access control model to determine object access by classification level?

Answers:

- Separation of duties
- Clearance
- ***Need to know**
- Ownership
- Principle of least privilege

Explanation:

Need to know is used with mandatory access control environments to implement granular control over access to segmented and classified data.

Separation of duties is the security principle that states that no single user is granted sufficient privileges to compromise the security of an entire environment.

Clearance is the subject classification label that grants a user access to a specific security domain in a mandatory access control environment.

Ownership is the access right in a discretionary access control environment that gives a user complete control over an object. This is usually because he or she created the object.

q_acct_bstpract_privilege_secp8

Which of the following is an example of privilege escalation?

Answers:

- ***Privilege creep**
- Principle of least privilege
- Separation of duties
- Mandatory vacations

Explanation:

Privilege creep occurs when a user's job position changes and he or she is granted a new set of access privileges for their new work tasks, but their previous access privileges are not removed. As a result, the user accumulates privileges over time that are not necessary for their current work tasks. This is a form of privilege escalation.

Separation of duties is the security principle that states that no single user is granted sufficient privileges to compromise the security of an entire environment.

Principle of least privilege and separation of duties are countermeasures against privilege escalation.

Mandatory vacations are used to perform peer reviews to help detect mistakes and fraud, and require cross-trained personnel.

q_acct_bstpract_rotation_secp8

You are concerned that the accountant in your organization might have the chance to modify financial information and steal from the company. You want to periodically have another person take over all accounting responsibilities to catch any irregularities.

Which security principle are you implementing by periodically shifting accounting responsibilities?

Answers:

- ***Job rotation**
- Need to know
- Principle of least privilege
- Explicit deny
- Separation of duties

Explanation:

Job rotation is a technique where users are cross-trained in multiple job positions and responsibilities are regularly rotated between personnel. Job rotation can be used for training purposes, but also allows for oversight of past transactions. As jobs rotate, personnel in new positions have the chance to review actions taken by others in that same position and catch security problems.

Separation of duties is the policy of requiring more than one person to complete a task.

The principle of least privilege states that users or groups are given only the access they need to do their job and nothing more.

With explicit deny, users are specifically prevented from gaining access to a resource.

Need to know describes the restriction of data that is highly sensitive and is usually referenced in government and military contexts.

q_acct_bstpract_separate_01_secp8

You want to make sure that any reimbursement checks issued by your company cannot be issued by a single person.

Which security principle should you implement to accomplish this goal?

Answers:

- ***Separation of duties**
- Mandatory vacations
- Job rotation
- Principle of least privilege

Explanation:

Separation of duties is the security principle that states that no single user is granted sufficient privileges to compromise the security of an entire environment.

Job rotation is a technique in which users are cross-trained in multiple job positions and responsibilities are regularly rotated between personnel. Job rotation is used for training purposes, but also allows for oversight of past transactions. As jobs rotate, personnel in new positions have the chance to review actions taken by others in that same position and catch security problems.

A requirement for mandatory vacations requires employees to take vacations of specified length. These vacations can be used to audit actions taken by the employee and provide a passage of time where problems caused by misconduct could become evident.

The principle of least privilege states that users or groups are given only the access they need to do their job and nothing more. With implicit deny, users or groups that are not specifically given access to a resource are denied access.

q_acct_bstpract_separate_02_secp8

Which security principle prevents any one administrator from having sufficient access to compromise the security of the overall IT solution?

Answers:

- Principle of least privilege
- ***Separation of duties**
- Dual administrator accounts
- Need to know

Explanation:

Separation of duties is the security principle that states that no single user is granted sufficient privileges to compromise the security of an entire environment. Usually, this principle is implemented by dividing administrative privileges among several administrators.

The principle of least privilege states that users should have the minimal amount of access necessary to perform their work tasks.

A dual-administrator accounts policy ensures that each administrator has a privileged-level account and a normal user-level account.

Need to know is an access control tool used in mandatory access control environments to implement granular control over access to segmented and classified data.

q_acct_bstpract_separate_03_secp8

What is the primary purpose of separation of duties?

Answers:

- Increase the difficulty of performing administrative duties.
- ***Prevent conflicts of interest.**
- Inform managers that they are not trusted.
- Grant a greater range of control to senior management.

Explanation:

The primary purpose of separation of duties is to prevent conflicts of interest by dividing administrative powers between several trusted administrators. This prevents a single person from having all of the privileges over an environment, which would create a primary target for attack and a single point of failure.

Increasing administrative difficulty, informing managers that they are not trusted, or granting a greater range of control to senior management are not the primary purposes of separation of duties. Separation of duties might seem to increase administrative difficulty, but this separation provides significant security benefits.

A manager is informed they are not trusted when they are not given any responsibility as opposed to a reasonable portion of responsibility.

Senior management already has full control over their organization.

q_acct_bstpract_something_you_have_secp8

After a breach, an organization implements new multi-factor authentication (MFA) protocols.

What MFA philosophy incorporates using a smart card or key fob to support authentication?

Answers:

- ***Something you have**
- Something you are
- Somewhere you are
- Something you know

Explanation:

Something you have means the account holder possesses something that no one else does, such as a smart card, key fob, or smartphone that can generate or receive a cryptographic token.

Something you are refers to a biometric or inherence factor. A biometric factor uses physiological identifiers, such as a fingerprint or facial scan, or behavioral identifiers, such as how someone moves (gait).

Somewhere you are means the system applies a location-based factor to an authentication decision. Location-based authentication measures some statistics about where you are.

Something you know means the information used for authentication is from something one can recall, such as a passphrase or username/password combination.

q_acct_bstpract_something_you_know_secp8

A cyber engineer conducts a multi-factor authentication (MFA) assessment of an organization's authentication security.

What MFA philosophy uses knowledge factors and includes passphrases to gain access to systems?

Answers:

- ***Something you know**
- Something you have
- Something you are
- Somewhere you are

Explanation:

Something you know means the information used for authentication is from something one can recall, such as a passphrase or username/password combination.

Something you have means the account holder possesses something that no one else does, such as a smart card, key fob, or smartphone that can generate or receive a cryptographic token.

Something you are refers to a biometric or inherence factor. A biometric factor uses physiological identifiers, such as a fingerprint or facial scan, or behavioral identifiers, such as how someone moves (gait).

Somewhere you are means the system applies a location-based factor to an authentication decision. Location-based authentication measures some statistics about where you are.

q_acc_models_abac_01_secp8

Which access control model is based on assigning attributes to objects and using Boolean logic to grant access based on the attributes of the subject?

Answers:

- ***Attribute-based access control (ABAC)**
- Mandatory access control (MAC)
- Role-based access control (RBAC)
- Rule-based access control

Explanation:

The ABAC model is based on assigning attributes to objects and using Boolean logic to grant access based on the attributes of the subject.

The MAC model is based on classification labels being assigned to objects and clearance labels being assigned to subjects. When a subject's clearance lines up with an objects classification, the subject is granted access.

The RBAC model grants access based on the subject's role in an organization.

The Rule-Based Access Control model grants access based on a set of rules or policies.

q_acc_models_abac_02_secp8

The IT department of an international organization is responsible for managing access controls to various sensitive resources and systems. The IT department aims to select the access control model that aligns BEST with the organization's security requirements, user roles, and data sensitivity levels.

Which access control model enforces permissions based on attributes and predefined rules, allowing the IT department to make fine-grained access decisions based on users' characteristics and data sensitivity within the multinational corporation?

Answers:

- ***Attribute-based access control (ABAC)**
- Rule-based access controls
- Discretionary access control (DAC)
- Role-based access control (RBAC)

Explanation:

Attribute-based access control (ABAC) enforces access permissions based on attributes, such as user attributes, resource attributes, and environmental conditions, allowing for fine-grained access control decisions.

Rule-based access controls rely on predefined rules without considering attributes, leading to less granular access control than ABAC.

Discretionary access control (DAC) gives users more control over resource access, which may not be suitable for managing fine-grained access decisions based on data sensitivity and user characteristics.

Role-based access control (RBAC) focuses on associating permissions with roles, not attributes, which is less suitable for fine-grained access control based on users' characteristics and data sensitivity within the organization.

q_acc_models_abac_03_secp8

A large multinational company uses a cloud-based document storage system. The system provides access to documents by considering a combination of factors: the user's department, geographic location, the document's sensitivity level, and the current date and time.

For example, only the finance department of a specific region can access its financial reports, and they can do so only during business hours.

Which access control model does the company MOST likely use to manage this complex access control?

Answers:

- ***Attribute-based access control (ABAC)**
- Rule-based access controls
- Discretionary access control (DAC)
- Role-based access control (RBAC)

Explanation:

Attribute-based access control (ABAC) enforces access permissions based on attributes, such as user attributes, resource attributes, and environmental conditions, allowing for fine-grained access control decisions.

Rule-based access controls (RBAC) rely on predefined rules without considering attributes, leading to less granular access control than attribute-based access control (ABAC).

Discretionary access control (DAC) gives users more control over resource access, which may not be suitable for managing fine-grained access decisions based on data sensitivity and user characteristics.

Role-based access control (RBAC) focuses on associating permissions with roles, not attributes, which is less suitable for fine-grained access control based on users' characteristics and data sensitivity within the organization.

q_acc_models_dac_01_secp8

You have a system that allows the owner of a file to identify users and their permissions to the file.

Which type of access control model is implemented?

Answers:

- ***Discretionary access control (DAC)**
- Mandatory access control (MAC)
- Role-based access control (RBAC)
- Rule-based access control

Explanation:

This is an example of a discretionary access control list (DACL), which uses the discretionary access control (DAC) model. With DAC, individuals use their own discretion (decisions or preferences) for assigning permissions and allowing or denying access.

Mandatory access control (MAC) uses labels for both subjects (users who need access) and objects (resources with controlled access). When a subject's clearance lines up with an object's classification, and when the user has a need to know (referred to as a category), the user is granted access.

Role-based access control (RBAC) allows access based on a role in an organization, not individual users. Roles are defined based on job description or a security access level. Users are made members of a role and receive the permissions assigned to the role.

Rule-based access control uses characteristics of objects or subjects along with rules to restrict access. Access control entries identify a set of characteristics that are examined for a match. If all characteristics match, access is either allowed or denied based on the rule.

q_acc_models_dac_02_secp8

Which form of access control enforces security based on user identities and allows individual users to define access controls over owned resources?

Answers:

- Role-based access control (RBAC)
- Mandatory access control (MAC)
- ***Discretionary access control (DAC)**
- Attribute-based access control (ABAC)

Explanation:

Discretionary access control (DAC) uses identities to control resource access. Users can make their own decisions about how much access to grant to other users.

Role-based access control (RBAC) allows access based on a role in an organization.

Mandatory access control (MAC) uses labels for both subjects and objects.

Attribute-based access control (ABAC) restricts access by assigning attributes to resources.

q_acc_models_least_privilege_01_secp8

In a medium-sized tech company, employees have different roles and responsibilities requiring access to specific resources and data. The IT team is implementing security measures to control access effectively and reduce the risk of unauthorized activities.

What security measure could the IT team implement in the tech company to control access effectively and minimize the risk of unauthorized activities?

Answers:

- ***The principle of least privilege, granting each employee the minimum necessary access based on job roles.**
- Implement a firewall to protect the company's network from external threats.
- Enforce mandatory password changes every month to enhance password security.
- Implement intrusion detection systems to monitor and identify potential security breaches.

Explanation:

The IT team is implementing the principle of least privilege, granting each employee the minimum necessary access based on job roles to control access effectively and minimize the risk of unauthorized activities.

Although implementing a firewall is an essential security measure, the scenario does not mention it as part of the access control measures.

Enforcing mandatory password changes can improve password security, but the scenario does not mention it as one of the measures implemented to control access.

Implementing intrusion detection systems is crucial for monitoring and identifying potential security breaches, but the scenario does not specify it as part of the access control measures.

q_acc_models_least_privilege_02_secp8

A new hire has just joined the IT department of a large organization. The human resources (HR) department assigns the employee an initial set of credentials for accessing the company network.

However, the new hire requires additional access to other systems within the company network.

Given this context, which of the following represents the MOST accurate example of implementing the principle of least privilege in this organization?

Answers:

- ***The IT department provides access to only a specific system requested by the new hire.**
- The IT department automatically grants the new hire access to all systems upon joining.
- The IT department grants full admin rights to the new hire after their first request.
- The IT department waits for a request from HR before granting any access to the new hire.

Explanation:

The principle of least privilege states that users should only have access to the resources necessary for their job roles.

Automatically granting the new hire access to all systems upon joining is against the principle of least privilege and leads to unnecessary security risks.

Granting full admin rights to the new hire after the first request is against the principle of least privilege. New hires should only have access to systems necessary for their jobs.

Waiting for a request from HR before granting any access does not necessarily follow the principle of least privilege. The IT department should base the decision on the requirements of the new hire's job role, not on a request from HR.

q_acc_models_least_privilege_03_secp8

What is the purpose of implementing the principle of least privilege in endpoint protection?

Answers:

- To restrict access to specific network resources.
- To enforce mandatory security configurations on devices.
- To manage firewall rules across an organization's network.
- ***To grant users, applications, and processes only the minimum necessary permissions.**

Explanation:

The purpose of implementing the principle of least privilege (PoLP) in endpoint protection is to grant users, applications, and processes the minimum necessary permissions required to perform their specific duties and tasks.

Restricting access to specific network resources is a general access control measure, but it is not specifically related to the principle of least privilege.

Enforcing mandatory security configurations on devices and managing firewall rules across an organization's network are both security measures for network security but do not relate directly to the principle of least privilege.

q_acc_models_least_privilege_04_secp8

One of your company's accountants submitted a ticket stating they could not access a particular section of the accounting software.

Why might the accountant not have access to every part of the accounting software?

Answers:

- Licensing
- DAC
- MAC
- ***Least privilege**

Explanation:

To increase the security posture of any given system, users should only have the necessary access (least privilege) to complete their work and nothing more.

Depending on the software, not having a specific license prevents users from accessing all of a given software. However, the most common reason is least privilege.

The resource owner has primacy in a discretionary access control (DAC) model. Every resource has an owner who creates a file or service, although another user can receive ownership assignment.

Security clearance levels form the basis of mandatory access control (MAC). Rather than defining access control lists (ACLs) on resources, each object receives a classification label. Depending on the clearance level, a subject receives access to that resource.

q_acc_models_least_privilege_05_secp8

A security analyst at a large organization aims to minimize the attack surface. To reach this goal, the analyst seeks to reduce the vulnerabilities an attacker can exploit, decrease the amount of code in use, and limit system interactions.

Which strategy should the security analyst implement to achieve this objective effectively?

Answers:

- Install the latest antivirus software
- Increase the complexity of user passwords
- ***Implement the principle of least privilege**
- Replace the wireless network with a wired network

Explanation:

Implementing the principle of least privilege ensures that users, systems, and processes have the minimum privileges needed to perform their tasks, thus reducing the attack surface.

Installing the latest antivirus software helps to detect and remove malicious software but does not necessarily limit the number of vulnerabilities an attacker can exploit.

Increasing the complexity of user passwords is part of a robust password policy, but it does not reduce the attack surface.

Although replacing the wireless network with a wired network might reduce certain attack vectors related to wireless security, it does not address the broader concept of minimizing the number of vulnerabilities, amount of code, or system interactions.

q_acc_models_least_privilege_06_secp8

A company acquires a smaller company and has its in-house technical team review the new systems before allowing them on the existing network.

During this review, the technical team discovers users with unnecessary permissions, user accounts for former employees, and no longer needed groups.

These discoveries indicate the violation of what BEST practice?

Answers:

- ***Principle of least privilege**
- Access control
- File system permissions
- Configuration enforcement

Explanation:

The principle of least privilege dictates that users, applications, and processes have the minimum permissions necessary to complete their duties and nothing more. This best practice helps ensure the security of the entire network.

Access control relates to the permissions granted to individuals, software, networks, or systems to allow one of these entries to complete authorized actions. It is not a best practice.

File system permissions are the permissions granted to each file based on an access control list (ACL). It is not a best practice.

Configuration enforcement ensures that systems and devices within a network have the same configuration, allowing for easier identification of compromised systems and ensuring a standard baseline.

q_acc_models_least_privilege_07_secp8

A financial services company tasks its IT security team with reducing the network's attack surface. They have segmented the network into security zones, put port security measures in place, and physically isolated critical servers.

The IT security team wants to further reduce the risk of attack by managing traffic flow between security zones.

Which of the following measures should the team implement?

Answers:

- ***Apply the principle of least privilege when defining traffic policies between zones.**
- Implement MAC filtering on all switch ports.
- Establish an air-gapped network for all company servers.
- Use a star network topology.

Explanation:

Least privilege can effectively reduce the attack surface by only allowing necessary communications between security zones, minimizing potential points of exploitation.

Media access control (MAC) filtering can help secure individual switch ports, but it does not directly affect the attack surface between security zones.

Air-gapped networks provide isolation but are impractical for most servers in companies that need to communicate with other networks. Also, it does not address traffic control between different security zones.

A flat or star network topology does not reduce the attack surface between security zones, but could increase attack surface within zones by allowing unrestricted exchange between nodes.

q_acc_models_location-based_secp8

An employee traveling in Europe for vacation submitted a ticket as they could not access their work email.

Which policy does the company use?

Answers:

- Password management
- Password age
- Multi-factor authentication
- ***Location-based authentication**

Explanation:

Location-based access policies would need a temporary exemption option to allow for travel. Location-based access policies prevent access to company systems outside a specified area (typically the company's state).

Password management would not aid in accessing a system set up to prevent access outside specific locations. However, it would provide a better way for employees to save passwords securely.

Password age would not help resolve issues accessing corporate resources from outside specific approved locations.

Multi-factor authentication would not help resolve issues with accessing corporate resources from outside specific approved locations.

q_acc_models_mac_01_secp8

Which type of access control focuses on assigning privileges based on security clearance and data sensitivity?

Answers:

- ***Mandatory access control (MAC)**
- Role-based access control (RBAC)
- Task-based access control (TBAC)
- Discretionary access control (DAC)

Explanation:

Mandatory access control (MAC) uses classifications to assign privileges based on security clearances and data sensitivity.

Role-based access control (RBAC) is a form of access control that assigns privileges based on a job description. New users are simply assigned a job label. The job label holds all the privileges necessary to accomplish the work tasks assigned to that job.

Task-based access control (TBAC) defines individual work tasks to assign privileges. It is similar to RBAC but with a primary difference. The difference is that a single user may be assigned dozens of tasks under TBAC, while under RBAC each user is only assigned a single job description.

With Discretionary access control (DAC), an administrator or owner defines user and resource access.

q_acc_models_mac_02_secp8

In which form of access control environment is access controlled by rules rather than identity?

Answers:

- Discretionary access control (DAC)
- ***Mandatory access control (MAC)**
- Access control list (ACL)
- Most client-server environments

Explanation:

A mandatory access control (MAC) environment controls access based on rules rather than identity.

Discretionary access control (DAC) environments use identity to control access.

Access control lists (ACLs) are a specific example of an identity-based access control mechanism used in DAC environments.

Most client-server environments use ACLs and, therefore, are DAC solutions.

q_acc_models_mac_03_secp8

The IT department of a governmental agency manages access controls for its various systems and resources. It is currently evaluating different access control models to enhance security across the enterprise. The organization deals with sensitive data, and it is crucial to have proper controls in place to protect the organization from unauthorized access.

The IT team considered several access control models, each offering distinct features, and the IT team analyzed which one aligns BEST with the organization's security requirements.

Which access control model enforces access permissions based on data sensitivity and predefined security labels, ensuring a higher level of control over sensitive resources in the organization?

Answers:

- ***Mandatory access control (MAC)**
- Discretionary access control (DAC)
- Role-based access control (RBAC)
- Attribute-based access control (ABAC)

Explanation:

Mandatory access control (MAC) enforces access permissions based on data sensitivity and predefined security labels. MAC restricts users' ability to change access permissions, ensuring higher resource control.

Discretionary access control (DAC) allows users to determine access permissions to resources owned. It does not focus on data sensitivity or predefined security labels.

Role-based access control (RBAC) assigns access permissions based on job roles and responsibilities. While it streamlines access management, it does not enforce control based on data sensitivity or predefined security labels.

Attribute-based access control (ABAC) enforces access permissions based on user characteristics, resource properties, and environmental factors. It provides a flexible and dynamic access control mechanism but does not explicitly focus on data sensitivity.

q_acc_models_mac_04_secp8

An international defense organization has developed a classified software system used for satellite communication. The system processes various levels of classified information: top secret, secret, and confidential.

The access to this system and its data is not determined by the individual user's wishes, a role, or by evaluating multiple attributes and conditions. Instead, the system enforces system access based on predefined classifications attached to subjects (users) and objects (data).

Which access control model is the defense organization MOST likely using?

Answers:

- ***Mandatory access control (MAC)**
- Discretionary access control (DAC)
- Role-based access control (RBAC)
- Attribute-based access control (ABAC)

Explanation:

Mandatory access control (MAC) enforces access permissions based on data sensitivity and predefined security labels. MAC restricts users' ability to change access permissions, ensuring higher resource control.

Discretionary access control (DAC) allows users to determine access permissions to resources owned. DAC does not focus on data sensitivity or predefined security labels.

Role-based access control (RBAC) assigns access permissions based on job roles and responsibilities. While RBAC streamlines access management, it does not enforce control based on data sensitivity or predefined security labels.

Attribute-based access control (ABAC) enforces access permissions based on user characteristics, resource properties, and environmental factors. ABAC provides a flexible and dynamic access control mechanism but does not explicitly focus on data sensitivity.

q_acc_models_provisioning_secp8

A recently hired information technology manager wants to implement more automation regarding the onboarding procedure.

What process describes setting up accounts so a new employee can automatically access the software and file shares from the human resource platform?

Answers:

- Multi-factor authentication
- Following least privilege
- Enabling a password reuse policy
- ***Provisioning**

Explanation:

Provisioning is the process of setting up a service according to a standard procedure or best practice checklist. Linking multiple systems together can increase the automation of onboarding procedures.

Multi-factor authentication is an authentication scheme that requires the user to present at least two different factors as credentials.

To increase the security posture of any given system, users should only have the necessary access (least privilege) to complete their work and nothing more.

The National Institute of Standards and Technology (NIST) recommends that people refrain from using passwords across multiple systems or services. However, this would not increase automation.

q_acc_models_rbac_01_secp8

Which form of access control is based on job descriptions?

Answers:

- Discretionary access control (DAC)
- Mandatory access control (MAC)
- ***Role-based access control (RBAC)**
- Attribute-based access control (ABAC)

Explanation:

RBAC is based on job descriptions.

DAC is based on identity.

MAC is based on rules.

ABAC restricts access by assigning attributes to resources.

q_acc_models_rbac_02_secp8

You have implemented an access control method that only allows users who are managers to access specific data.

Which type of access control model is being used?

Answers:

- ***Role-based access control (RBAC)**
- Mandatory access control (MAC)
- Discretionary access control (DAC)
- Discretionary access control list (DACL)

Explanation:

Role-based access control (RBAC) allows access based on a role in an organization, not individual users. Roles are defined based on job description or a security-access level. Users are made members of a role and receive the permissions assigned to the role.

Discretionary access control (DAC) assigns access directly to subjects based on the discretion of the owner. Objects have a discretionary access control list (DACL) with entries for each subject. Owners add subjects to the DACL and assign rights or permissions. The permissions identify the actions the subject can perform on the object.

Mandatory access control (MAC) uses labels for both subjects (users who need access) and objects (resources with controlled access). When a subject's clearance lines up with an object's classification, and when the user has a need to know (referred to as a category), the user is granted access.

q_acc_models_rule_based_secp8

In a medium-sized company, the IT department manages access to various systems and resources for employees. The team wants to enhance the security posture by implementing better access controls. They use rule-based access controls and time-of-day restrictions to achieve this goal.

What are the IT department's objectives in implementing rule-based access controls and time-of-day restrictions? (Select two.)

Answers:

- ***To define specific access rules based on employees' roles and responsibilities.**
- ***To restrict access to critical systems during non-working hours to enhance security.**
- To ensure all employees have access to all resources at any time for increased productivity.
- To eliminate the need for user authentication and simplify access management.
- To ensure that all employees are biometrically verified.

Explanation:

The IT department aims to implement rule-based access controls to define specific access rules based on employees' roles and responsibilities, ensuring users can access only the resources they need to fulfill their job duties and enhance security.

The implementation of time-of-day restrictions limits access to critical systems during non-working hours, which helps improve security by reducing exposure to potential threats when fewer employees are present.

Allowing all employees to access all resources without restrictions poses significant security risks, violates the principle of least privilege, and increases the attack surface.

Implementing rule-based access controls and time-of-day restrictions does not aim to eliminate user authentication; rather, it complements user authentication mechanisms.

Biometrics are a type of authentication and do not apply to rule-based access controls.

q_acc_models_rule_secp8

Which of the following is an example of rule-based access control?

Answers:

- ***Router access control lists that allow or deny traffic based on the characteristics of an IP packet.**
- A subject with a government clearance that allows access to government classification labels of Confidential, Secret, and Top Secret.
- A member of the accounting team that is given access to the accounting department documents.
- A computer file owner who grants access to the file by adding other users to an access control list.

Explanation:

A router access control list that allows or denies traffic based on the characteristics of an IP packet is an example of rule-based access control.

A subject with a government clearance that allows access to government classification labels of Confidential, Secret, and Top Secret is an example of mandatory access control.

A member of the accounting team that is given access to the accounting department documents is an example of role-based access control.

A computer file owner who grants access to the file by adding other users to an access control list is an example of discretionary access control.

q_acc_models_teach_awareness_secp8

You are a system administrator for a large corporation. A new employee, John, has just joined the marketing team and you are tasked with provisioning his user account.

John is not very familiar with the company's IT policies and procedures.

What should be your first step in this process?

Answers:

- Assign John the same privileges as the rest of the marketing team.
- ***Teach John about the company's IT policies and the importance of policy awareness.**
- Create a user account for John with full administrative privileges.
- Provide John with a list of all the software he will need to install on his computer.

Explanation:

Before provisioning John's account, it's crucial to ensure he understands the company's IT policies and the importance of policy awareness. This will help him understand his responsibilities, the limitations of his account, and the potential consequences of policy violations. This is the correct answer as it emphasizes the importance of policy awareness before account provisioning.

Assigning John the same privileges as the rest of the marketing team might seem like a logical step, but without understanding the company's IT policies, John might misuse or not fully understand his privileges, which could lead to security risks.

Creating a user account for John with full administrative privileges is not a recommended practice. This could lead to serious security risks, especially if John is not familiar with the company's IT policies.

Providing John with a list of all the software he will need to install on his computer is a task that should be done after his account has been provisioned and he has been made aware of the company's IT policies. This is not the first step in the process.

q_acc_models_time-based_01_secp8

A contractor only works for a company from 9 a.m. to 12 p.m.

What kind of restriction could the company set up on the contractor's account to prevent using it outside that range?

Answers:

- Location-based restrictions
- Password restrictions
- ***Time-based restrictions**
- Mandatory access control

Explanation:

A time-based restriction would prevent access to corporate resources outside a set schedule. The company should set this account policy.

Location-based access policies would need a temporary exemption option to allow for travel. Location-based access policies prevent access to company systems outside a specified area (typically the company's state).

Password policies would not help prevent access to systems for the contractor during the slated schedule.

Security clearance levels form the basis of mandatory access control (MAC). Rather than defining access control lists (ACLs) on resources, each object receives a classification label. Depending on the clearance level, a subject receives access to that resource.

q_acc_models_time-based_02_secp8

As a network security administrator, you have implemented various access control models in your organization.

One day, you notice that an employee's account has been accessed from two different geographical locations within a time frame that would be impossible for the employee to travel.

The locations are New York and Tokyo, and the logins occurred within an hour of each other.

What should be your immediate course of action?

Answers:

- Ignore the logins as it might be a system error.
- ***Immediately disable the account and investigate the logins.**
- Contact the employee and ask if they shared their login credentials.
- Change the password of the employee's account.

Explanation:

Disabling the account immediately prevents any further potential unauthorized access. Investigating the logins can help determine if it was a case of credential sharing, a system error, or a potential security breach. This is the correct course of action as it addresses the issue of impossible travel time/risky login policy.

Ignoring the logins could potentially allow unauthorized access to continue, which could lead to data breaches or other security incidents. This is not a recommended course of action.

While contacting the employee is a good step, it should not be the immediate action. The account should first be secured to prevent any potential unauthorized access. Furthermore, if the employee has indeed shared their credentials, they might not be truthful about it.

Changing the password might prevent further unauthorized access, but it does not address the potential security breach that has already occurred. Also, if the unauthorized user has access to the employee's email, they could potentially reset the password again.

4.2 Authentication

As you study this section, answer the following questions:

- What is the difference between authentication factors and attributes?
- What is an example of the "something you are" authentication type?
- What is an example of the "something you have" authentication type?
- What is multi-factor authentication?
- Which physical attributes can be used to identify an individual?

In this section, you will learn to:

- Use a biometric scanner
- Use single sign-on

The key terms for this section include:

Term	Definition
Multi-factor authentication (MFA)	An authentication scheme that requires the user to present at least two different factors as credentials; for example, something you know, something you have, something you are, something you do, and somewhere you are. Specifying two factors is known as 2FA.
Factors	In authentication design, different technologies for implementing authentication, such as knowledge, ownership/token, and biometric/inherence. These are characterized as something you know/have/are.
Personal identification number (PIN)	A number used in conjunction with authentication devices such as smart cards; as the PIN should be known only to the user, loss of the smart card should not represent a security risk.
Hard authentication token	Authentication token generated by a cryptoprocessor on a dedicated hardware device. As the token is never transmitted directly, this implements an ownership factor within a multi-factor authentication scheme.
Smart cards	A security device similar to a credit card that can store authentication information, such as a user's private key, on an embedded cryptoprocessor.
One-time password (OTP)	A password that is generated for use in one specific session and becomes invalid after the session ends.

Term	Definition
Security key	Portable HSM with a computer interface, such as USB or NFC, used for multi-factor authentication.
Soft authentication token	OTP sent to a registered number or email account or generated by an authenticator app as a means of two-step verification when authenticating account access.
Passwordless	Multi- factor authentication scheme that uses ownership and biometric factors, but not knowledge factors.
Attestation	Capability of an authenticator or other cryptographic module to prove that it is a root of trust and can provide reliable reporting to prove that a device or computer is a trustworthy platform.
NT LAN Manager (NTLM) authentication	A challenge-response authentication protocol created by Microsoft for use in its products.
Pluggable authentication module (PAM)	A framework for implementing authentication providers in Linux.
Directory service	A network service that stores identity information about all the objects in a particular network, including users, groups, servers, client computers, and printers.
Lightweight Directory Access Protocol (LDAP)	Protocol used to access network directory databases, which store information about authorized users and their privileges, as well as other organizational information.
Distinguished name (DN)	A collection of attributes that define a unique identifier for any given resource within an X.500-like directory.
Single sign-on (SSO)	Authentication technology that enables a user to authenticate once and receive authorizations for multiple services.
Kerberos	A single sign-on authentication and authorization service that is based on a time-sensitive, ticket-granting system.
Key distribution center (KDC)	A component of Kerberos that authenticates users and issues tickets (tokens).

Term	Definition
Ticket Granting Ticket (TGT)	In Kerberos, a token issued to an authenticated account to allow access to authorized application servers.
Federation	A process that provides a shared login capability across multiple systems and enterprises. It essentially connects the identity management services of multiple systems.
Identity provider (IdP)	In a federated network, the service that holds the user account and performs authentication.
Security Assertion Markup Language (SAML)	An XML-based data format used to exchange authentication information between a client and a service.
Simple Object Access Protocol (SOAP)	An XML-based web services protocol that is used to exchange messages.
Representational State Transfer (REST)	A standardized, stateless architectural style used by web applications for communication and integration.
Open Authorization (OAuth)	A standard for federated identity management, allowing resource servers or consumer sites to work with user accounts created and managed on a separate identity provider.
JavaScript Object Notation (JSON)	A file format that uses attribute-value pairs to define configurations in a structure that is easy for both humans and machines to read and consume.
Biometric authentication	An authentication mechanism that allows a user to perform a biometric scan to operate an entry or access system. Physical characteristics stored as a digital data template can be used to authenticate a user. Typical features used include facial pattern, iris, retina, fingerprint pattern, and signature recognition.
False Rejection Rate (FRR)	A biometric assessment metric that measures the number of valid subjects who are denied access.
False Acceptance Rate (FAR)	A biometric assessment metric that measures the number of unauthorized users who are mistakenly allowed access.
Crossover Error Rate (CER)	A biometric evaluation factor expressing the point at which FAR and FRR meet, with a low value indicating better performance.

This section helps you prepare for the following certification exam objectives:

4.2.1 Authentication (Lesson Video)

Transcript:

In this video, we'll discuss authentication. Authentication involves verifying a claimed identity. To verify an identity, we need some unique information or data that could only come from that individual.

Three main factors are used in authentication: something you know, something you have, and something you are.
First, let's look at something you know. This commonly used authentication method is knowledge-based. It requires the user to provide information that only they know. The most familiar example is a password. The password is something that only the user should know for their authentication.
A PIN is another example of something you know authentication. Unlike a password, a PIN is limited to numerical digits.
Another example is cognitive information. This is when a question is provided that only the user can answer. Often, for account recovery methods, a company will ask users to supply answers to specific questions, such as your mother's maiden name or the name of your first pet.
The next authentication type, something you have, is sometimes called token-based authentication. Hard tokens require the user to possess a physical factor—an object such as a smart card, key fob, or a USB device—that can be used for authentication. Soft tokens are software that can be installed on a user's smartphone, tablet, or computer.
Soft tokens generate one-time passwords (OTPs) that are used for authentication. When users attempt to log in, they must enter their username and password and then generate or receive an OTP from the soft token application. The OTP is time-limited and changes periodically, usually every 30 seconds. This adds an extra layer of security since OTP is unique for each login attempt and cannot be easily replicated or reused by an attacker.
The third factor, something you are, refers to physiological attribute biometrics. Your fingerprint, retinal scan, vein scan, face scan, or voice print will prove that you are who you say you are.
On their own, some of these authentication methods could be easily compromised. A password can be written down, guessed, or shared. A smart card can be lost or stolen. When two or more of these factors are combined, this is known as multifactor authentication. When the requirement for a password is combined with a token-generated PIN or combined with a fingerprint scan, accessing an account becomes much more complicated. With Multifactor authentication, a username and password can be breached but are unusable without the additional factor!
While we've talked about the three main authentication factors, other factors can be used to help validate authentication: somewhere you are, something you do, something you exhibit, and someone you know. While these may not verify a user's identity independently, they help improve security and work well in multifactor authentication settings.
Somewhere you are authentication uses a physical location to verify a user's identity. For example, you may have a desktop system configured to allow authentication requests only if the user has passed through the building's entrance using their ID card. If the user tries to log in to the desktop, the system will look to see if the user has entered the building. If not, the user's account is locked.
The location could be determined using radio-frequency identification or an RFID proximity reader. If the user is within range, they're authenticated to the system. The user moving out of range automatically locks the system.
GPS location data can also be used to unlock mobile devices. For example, your phone can be automatically unlocked within a specific geographical area. If it moves outside that location, it will be locked and require a PIN or password to unlock. Bluetooth can also be used for this type of authentication. If you're in range of a device via Bluetooth, you can configure your mobile device to unlock itself automatically.
Another authentication type is something you do. This type requires the user to perform a particular action to verify the user's identity. For example, the user might be required to supply a handwriting sample analyzed against a baseline

sample. It could also require a typing test, where the user must type some sample text, and their typing behaviors are analyzed against a baseline sample.
Another attribute could be something you exhibit, such as a personality trait or a habit. Authentication systems can note the time of day you usually log on, your access method, or the tasks you often perform. When administrators notice unusual activity or risky behavior, they may restrict access to these users. This could mean requiring a password change, another authentication method, or blocking user access.
Another authentication factor is someone you know. You've probably heard the phrase, "It's not what you know, it's who you know." Having someone who can vouch for you can go a long way to establishing relationships and building trust. The same is true for authentication. An example of this trust is certificates.
Certificate authorities issue certificates to organizations that they trust. These organizations are intermediary certificate authorities who then issue certificates to their users. This creates a chain of trust that verifies that the subject named in the certificate can be trusted and has been verified by a certificate authority. Certificates are commonly used for logging into secure sites or signing documents electronically.
That's it for this lesson. In this lesson, we discussed the three main factors of authentication. These include something you know, something you have, and something you are. We also discussed other authentication factors, such as somewhere you are, something you do, something you exhibit, and someone you know.

4.2.2 Authentication Factors Facts

Assuming that an account has been created securely and the identity of the account holder has been verified, authentication verifies that only the account holder is able to use the account and that the system may only be used by account holders. Authentication technologies allow the use not only of passwords but also of biometric and token factors to better secure accounts. Understanding the strengths and weaknesses of these factors will help you to implement and maintain strong authentication systems.

This lesson covers the following topics:

- Authentication design
- Multifactor authentication
- Authentication factors

Authentication Design

To access resources on a network, you must prove who you are and have the required permissions. This process consists of the following elements:

- *Identification* is the initial process of confirming your identity when you request credentials. It occurs when you enter a user ID to log on. Identity proofing occurs during the identification phase as you prove that you are who you say you are to obtain credentials. Suppose you have been identified previously but cannot provide the assigned authentication credentials (such as a lost password). In that case, identity proofing is called upon again.
- *Authentication* is the verification of the issued identification credentials. It is usually the second step in the identification process. It establishes your identity, ensuring that you are who you say you are.

Identity is as simple as telling someone your name. In the computer world, a username is a form of identification. Identification alone is not very secure because anyone could pretend to be you. To substantiate your identity, you need to provide some verification that you are who you say you are. The following chart provides a few of the basics of identity authentication.

Term	Description
Identity provider (IdP)	An identity provider is an online service that manages identity information for other organizations. The IdP creates records from an organization's existing data and policies. These records are used to authenticate user requests.
Attributes	Attributes can be your role, position, or current project. This information can be used to determine policy and permission.
Certificates	Certificates are issued by a certificate authority and verify identity by providing the following: • Public keys • Details on the owner of the certificate • Details on the issuer of the certificate
Tokens	A token is a device or a file used to authenticate. A hardware token, such as a key fob, serves as something you have. A software token (or a soft token) is stored in devices such as laptops, desktops, or mobile phones. These tokens are specific to the device and cannot be altered or duplicated.
SSH keys	A secure shell (SSH) key is an access credential. It operates like usernames and passwords but is mainly used to implement single sign-on and other automated processes.

Authentication is performed when a supplicant or claimant presents credentials to an authentication server. The server compares what was presented to the copy of the credentials it has stored. If they match, the account is authenticated. *Authentication design* refers to selecting a technology that meets requirements for confidentiality, integrity, and availability:

- **Confidentiality** , in terms of authentication, is critical because if account credentials are leaked, threat actors can impersonate the account holder and act on the system with whatever rights they have.
- **Integrity** means that the authentication mechanism is reliable and not easy for threat actors to bypass or trick with counterfeit credentials.
- **Availability** means that the time taken to authenticate does not impede workflows and is easy enough for users to operate.

Multifactor Authentication

An authentication design that uses only passwords or a single knowledge factor is considered weak. Password secrets are too prone to compromise to be reliable. Other types of authentication factors can be used to supplement or replace password-based logins. A multifactor authentication (MFA) technology combines the use of more than one type of factor.

Multifactor authentication requires a combination of different technologies. For example, requiring a PIN along with a date of birth may be stronger than entering a PIN alone, but it is not multifactor.

You might also see references to two-factor authentication (2FA) . This just means that there are precisely two factors involved, such as an ownership-based smart card or biometric identifier with something you know, such as a password or PIN.

Authentication Factors

There are many different technologies for defining credentials. These can be categorized as factors .

Something You Know Factor

The longest-standing authentication factor is "Something You Know," or a knowledge factor. The typical knowledge factor is the *login* , composed of a username and a password. This is the weakest type of authentication because both items are something you know, but this is also the most used.

The username is typically not a secret (although it should not be published openly), but the password must be known only to the account holder. Only the passwords or other information associated with the usernames can be used to validate identity. A passphrase is a longer password composed of several words. This has the advantages of being more secure and easier to remember. Composition passwords are created by the system and are usually two or more unrelated words divided by symbols on the keyboard. A final example is cognitive information, such as questions you can only answer, such as your mother's maiden name, the model of your first car, or the city where you were born.

Windows sign-in screen. (Screenshot used with permission from Microsoft.)

A personal identification number (PIN) is also something you know. Originally, PINs were associated with short four- or six-digit numeric sequences used with bank cards. In modern authentication designs, the main characteristic of a PIN is that it is valid for authenticating to a single device only. This type of PIN can use any character and be any length.

Something You Are Factor

Something you are refers to a biometric or inherence factor. A *biometric factor* uses either physiological identifiers, such as a fingerprint or facial scan, or behavioral identifiers, such as the way someone moves (gait). The identifiers are scanned and recorded as a template. When the user authenticates, another scan is taken and compared to the template. This is one of the more secure forms of authentication and one of the most expensive.

Somewhere You Are Factor

Somewhere you are (also known as geolocation) means the system applies a location-based factor to an authentication decision. Location-based authentication measures some statistics about where you are. This could be a physical geographic location measured using a device's location service or Internet Protocol (IP) network address. A device's IP address could be used to refer to a logical network segment, or it could be linked to a geographic location using a geolocation service. Within a premises network, the physical port location, virtual LAN (VLAN), or Wi-Fi network can also be made the basis of location-based authentication.

Location-based authentication is not used as a primary authentication factor, but it may be used as a continuous authentication mechanism or as an access control feature. For example, if a user enters the correct credentials at a remote access gateway, but their IP address shows them to be in a different country than expected, access controls might be applied to restrict the privileges granted or refuse access completely. Another example is when a user appears to log-in from multiple geographic locations that would be physically impossible with travel time.

Examples of implementations include:

- A desktop system configured to allow authentication requests only if you have passed through the building's entrance using your ID card. If you are not in the building, your account is locked.
- A system configured with an RFID proximity reader and required RFID badges. Authentication requests are allowed if you are within the workstation's RFID range. If you move out of range, the workstation is immediately locked. Reauthentication is not allowed until you move back within range.
- GPS location data is used to determine a device's location. Authentication requests are allowed if you and the device are in a specified location. If not, the device is locked, or additional authentication factors are requested.
- Wi-Fi triangulation is used to determine a device's location. Authentication requests are allowed if you and the device are in a specified location. If not, the device is locked, or additional authentication factors are requested.

Something You Can Do Factor

Something you can do requires performing a particular action to verify your identity. Here are a few examples of an action that can be used:

- Supply a handwritten sample that’s analyzed against a baseline sample for authentication.
- Type sample text. Your typing behaviors are analyzed against a baseline before authentication.

Something You Exhibit Factor

Something that you exhibit could include a personality trait or a habit. For example:

- The time of day you usually log on.
- The method you typically use to access information.
- The types of tasks you usually perform.

When administrators notice unusual or risky behavior, they may restrict access. This could mean requiring a password change, another authentication method, or blocking access.

Someone You Know Factor

Having someone who can vouch for you can go a long way in establishing relationships and building trust. The same is valid with authentication. Certificates and attestation are examples of this attribute.

Something You Have Factor

Something you have is an *ownership factor* . It means that the account holder possesses something that no one else does. The term token-based authentication is often used to describe this factor due to the use of security tokens. Some examples include:

- Swipe cards (like credit cards) with authentication information stored on the magnetic strip.
- Photo IDs are handy when combined with other forms of authentication. Still, they are high risk if they are the only form of required authentication. Photo IDs are easily manipulated or reproduced, require personnel for verification, and cannot be verified against a system.
- Key fobs are small, programmable hardware often used to access buildings and open doors. Key fobs are usually attached to a keychain.
- Security tokens generate a unique password when activated manually. These passwords are used once and usually expire in minutes.
- Smart cards contain a memory chip with encrypted authentication information.
- Smartphone that can generate or receive a cryptographic token.

An ownership factor means that the user possesses some type of device that only they can operate. This is referred to as an authenticator. The authenticator is able to generate or receive a token that identifies and authenticates the user. There are three main types of token generation:

- **Certificate-based authentication** — is when the supplicant controls a private key that can generate a unique signed token. The identity provider can verify the signature via the public key. The main drawback of this approach is the administrative burden of implementing PKI to issue digital certificates.
- **One-time password (OTP)** — is when a token is generated using some sort of hash function on a shared secret value plus a synchronization seed, such as a timestamp (TOTP) or HMAC (HOTP). The token can only be used once. A new token is generated for each authentication decision. This approach still uses a key pair and hashing for security, but it does not require PKI.
- **Fast IDentity Online (FIDO) Universal 2nd Factor (U2F)** — uses a public/private key pair to register each account, avoiding the need to communicate a shared secret, a weakness of HOTP and TOTP. The private key is locked to the U2F device and signs the token; the public key is registered with the authentication server and verifies the token. As no digital certificates are involved, the solution does not rely on PKI.

A hard authentication token is generated within a secure cryptoprocessor. The authentication design means that there is no transmission of the token itself. Several device-based authenticators can be used to implement hard tokens:

- **Smart cards** — implement certificate-based authentication. A certificate is a digital document associated with a user as a one-to-one or many-to-one mapping. In a one-to-one mapping, each certificate maps to an individual user account (each user has a unique certificate). With many-to-one mapping, a certificate maps to many user accounts (a group of users shares the same certificate). The smart card stores the user's digital certificate, the private key associated with the certificate, and a personal identification number (PIN) used to activate the card. The card must be presented to a reader. There are physical contact and contactless near-field communication (NFC) card types.
- **One-time password (OTP)** — refers to a cryptoprocessor that can generate a token. This type of hardware token does not need an interface to connect with a computer; the user just reads the code displayed.

- **Security key** — refers to a portable hardware security module (HSM) with a computer interface, such as USB or NFC. They are most closely associated with U2F, but some might also support certificate-based authentication or HOTP/TOTP. A security key must be activated to show presence. Some keys just have an activation button, but most use a biometric fingerprint reader for better security. A PIN must also be configured as a backup mechanism.

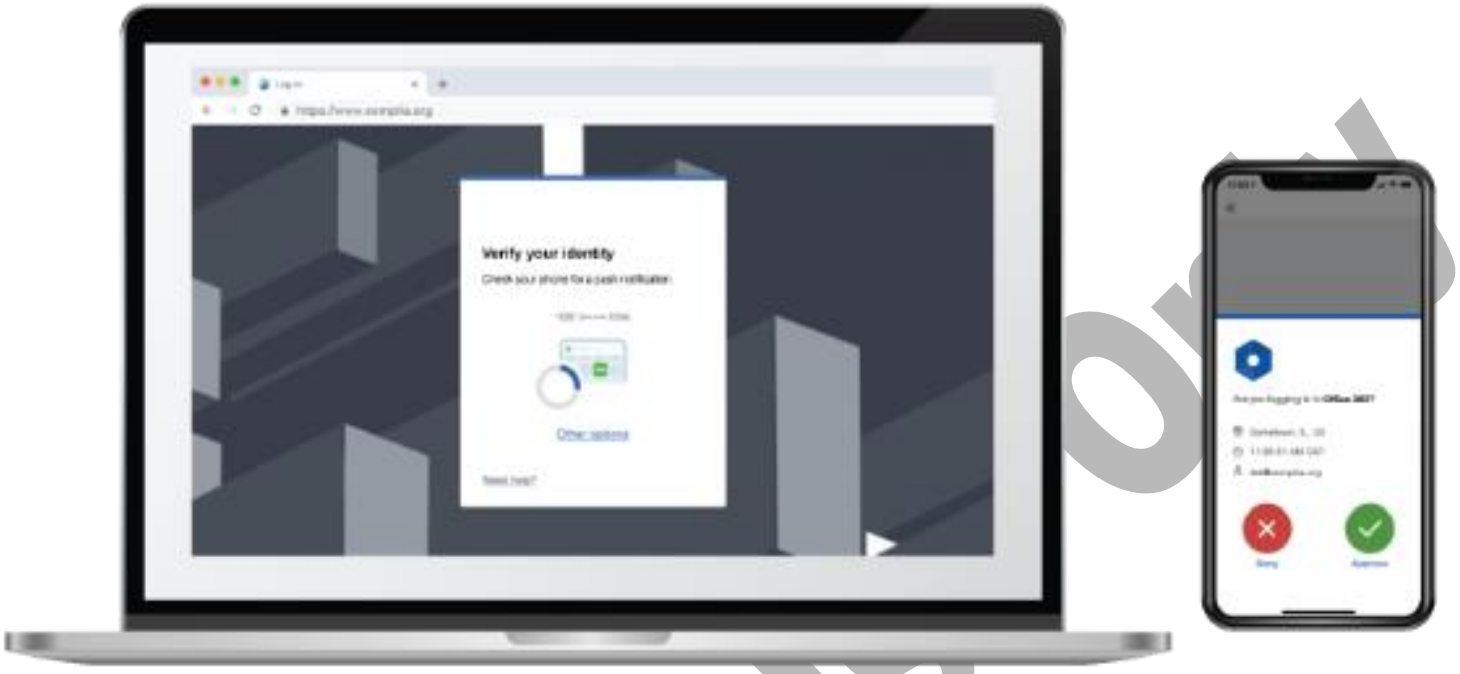
Key fob token generator. (Image © 123RF.com.)

There are also simpler smart cards and fobs that simply transmit a static token programmed into the device. For example, many building entry systems work on the basis of static codes. These mechanisms are highly vulnerable to cloning and replay attacks.

A soft authentication token is a one-time password generated by the identity provider and transmitted to the supplicant. The OTP could be sent to a registered phone number as an SMS/text message or to an email account. This method is more likely to use counter-based tokens, though they will still have an expiry period.

Soft tokens sent via SMS or email do not really count as an ownership factor. These systems can be described as two-step verification rather than MFA. The tokens are highly vulnerable to interception.

A more secure soft OTP token can be generated using an authenticator app. This is software installed on a computer or smartphone. The user must register each identity provider with the app, typically using a scannable quick response (QR) code to communicate the shared secret. When prompted to authenticate, the user must unlock the authenticator app with their device credential to view the OTP token. There is less risk of interception than with an SMS or email message, but as it runs on a shared-use device, there is the possibility that malware could compromise the app.



Using an authenticator app to sign in to a site. After the user signs in with a password, the site prompts them to authorize the sign-in using the authenticator app installed on their smartphone.

With token-based MFA, the user account is typically still configured with a password. This might be used as a backup mechanism, or there might be a two-step verification process where the user must enter their password and then submit an OTP.

Passwordless means that the whole authentication system no longer processes knowledge-based factors. The FIDO2 with WebAuthn specifications provides a framework for passwordless authentication. It works as follows:

- The user chooses either a roaming authenticator, such as a security key, or a platform authenticator implemented by the device OS, such as Windows Hello or Face ID/Touch ID for macOS and iOS.
- The user configures a secure method or local gesture to confirm presence and authenticates the device. This gesture could be a fingerprint, face recognition, or PIN. This credential is only ever validated locally by the authenticator.
- The user registers with a web application or service, referred to as a relying party. For each new relying party, the authenticator generates a public/private key pair. The user's client browser obtains the public key from the authenticator and registers it to associate it with an account on the relying party.
- When presented with an authentication challenge, the user performs the local gesture to unlock the private key. The private key is used to sign a confirmation that the local gesture worked, which is then sent to the relying party.
- The relying party uses the public key to verify the signature and authenticate the account session.

As with FIDO U2F, this provides similar security to smart card authentication but does not require accounts to have digital certificates and PKI, reducing the management burden. FIDO2 WebAuthn improves on FIDO U2F by adding an application programming interface (API) that allows web applications to work without a password element for authentication. Most FIDO U2F authenticators should also support FIDO2/WebAuthn.

For a passwordless system to be secure, the authenticator must be trusted and resistant to spoofing or cloning attacks. **Attestation** is a mechanism for an authenticator device, such as a FIDO security key or the TPM in a PC or laptop, to prove that it is a root of trust. Each security key is manufactured with an attestation and model ID. During the registration step, if the

relying party requires attestation, the authenticator uses this key to send a report. The relying party can check the attestation report to verify that the authenticator is a known brand and model and supports whatever cryptographic properties the relying party demands.

Note that the attestation key is not unique; if it were unique, it would be easy to identify individuals and be a serious threat to privacy. Instead, it identifies a particular brand and model.

4.2.3 Authentication Methods (Lesson Video)

Transcript:

A user must provide the correct credentials to authenticate a system, usually a username and password. After that, the system checks an access service or protocol to ensure a match with existing credentials. The authentication process itself doesn't determine your authorization level. In other words, authentication doesn't determine what you can access; it only defines who you are. The application determines your authorization level and what you can do with the application only after you authenticate to the system. Let's look at a few authentication methods you need to know as a security professional.

Single sign-on, or SSO, is an authentication process that allows users to access multiple systems, applications, websites, and other resources using only a single set of credentials. With SSO, a user authenticates once using designated credentials and can access different resources seamlessly.
Imagine that you need to log into your workstation, log into the company portal, log in to check your emails, and then log in again to access your video conferencing software. Instead of assigning four different credentials, it would be better to implement an SSO. Since this service shares authentication sessions between systems, you automatically receive access to all the sessions if you log into one.
While SSO dramatically improves usability, it comes with the risk that breached credentials can be used to gain access to a wide array of resources. Considering SSO provides powerful, seamless access to a wide range of sensitive systems and data using only a single set of credentials, multifactor authentication methods should be coupled with SSO to prevent credentials from being easily abused and stolen.
Directory services provide a single sign-on location for multiple network resources. Examples include Microsoft's Active Directory and LDAP directory services. Directory services' users sign on with a domain user account to gain access to available domain resources.
Another authentication method is OAuth. Although OAuth works closely with authentication services, it doesn't provide authentication services itself. Instead, OAuth provides authorization services. In other words, it authorizes an entity to obtain information but doesn't verify the entity itself. OAuth lets a third party access a user's information from another website without a password. It acts as an intermediary between two entities and provides access tokens that manage the exchange of specific information.
OAuth has a few main components. It starts with a user wanting to access multiple apps without creating many new accounts. Next, you need the client software app on a computer, mobile phone, or any other smart device. You also need a resource server that the user and client are trying to access and an authorization server that provides a token for the user and client to access the resource server.
Let's say that I just installed an app onto my phone. When I open the new app, I'm prompted to log in using my Facebook or Google account. I decide to use my Facebook account, so I'm redirected to Facebook's authorization server to get an access token. The authorization server authenticates you as the user, and the app uses OAuth to grant an access token with precise information from the app. Now, when the app goes to the resource server with that token, you're registered and logged into the app with limited access to your Facebook information.
So, where's the authentication? Well, that's where OpenID Connect, or OIDC, comes in. OIDC is built on the OAuth framework and provides the needed authentication service. Remember, OAuth only provides authorization. OIDC takes it a step further and provides identity authentication. OIDC also accesses stored personal information and preferences from an identity layer that the user has previously disclosed. This layer provides the website with the user's information, where, when, and how of the authentication, and which attributes the user wants to share with that specific website and why. Big companies like Google and Microsoft use OIDC, so it's secure and reliable.
Another authentication method is a federation. A federation is a group of domains that established enough trust to share authorizations with each other. A federation can be used within a single organization with multiple domains or include

several trusted organizations that want to pool their resources. The good thing about this authentication method is that everything's on-site, providing the administration with detailed access control levels.
Another authentication method is attestation. Attestation is a protocol that proves that software can be trusted. It tells the remote user that the software is legitimate and certified. Attestation usually works in both parties' interest.
For example, say I was going to log into my bank account. I'd want to be sure that the site that I'm logging into is trustworthy, and the bank would like to be sure that I am really the one who is trying to log into my account.
That's it for this lesson. In this lesson, we talked about several different authentication methods. These include single sign-on, directory services, Oauth, federation, and attestation. As a security professional, knowing and understanding these authentication methods will benefit you immensely in your future endeavors.

4.2.4 Authentication Methods Facts

While an on-premises network can use a local directory to manage accounts and rights, as organizations move services to the cloud, these authorizations have to be implemented using federated identity management solutions.

This lesson covers the following topics:

- Local, network, and remote authentication
- Windows authentication
- Linux authentication
- Directory services
- Single sign-on authentication
- Federation
- Open authorization

Local, Network, and Remote Authentication

One of the most important features of an operating system is the *authentication provider* , which is the software architecture and code that underpins the mechanism by which the user is authenticated before starting a shell.

Knowledge-based authentication relies on cryptographic hashes. A plaintext password is not usually transmitted or stored in a credential database because of the risk of compromise. Instead, the password is stored as a cryptographic hash. When a user enters a password to log in, an authenticator converts what is typed into a hash and transmits that to an authority. The authority compares the submitted hash to the one in the database and authenticates the subject only if they match.

Windows Authentication

Windows authentication involves a complex architecture of components (docs.microsoft.com/en-us/windows-server/security/windows-authentication/credentials-processes-in-windows-authentication), but the following three scenarios are typical:

- **Windows local sign-in** — is the Local Security Authority Subsystem Service (LSASS) that compares the submitted credential to a hash stored in the Security Accounts Manager (SAM) database, which is part of the registry. This is also referred to as *interactive logon* .
- **Windows network sign-in** — is LSASS, which can pass the credentials for authentication to an Active Directory (AD) domain controller. The preferred system for network authentication is based on Kerberos, but legacy network applications might use NT LAN Manager (NTLM) authentication .
- **Remote sign-in** — is used if the user's device is not directly connected to the local network. Authentication can take place over a virtual private network (VPN), enterprise Wi-Fi, or web portal. These use protocols to create a secure connection between the client machine, the remote access device, and the authentication server.

Linux Authentication

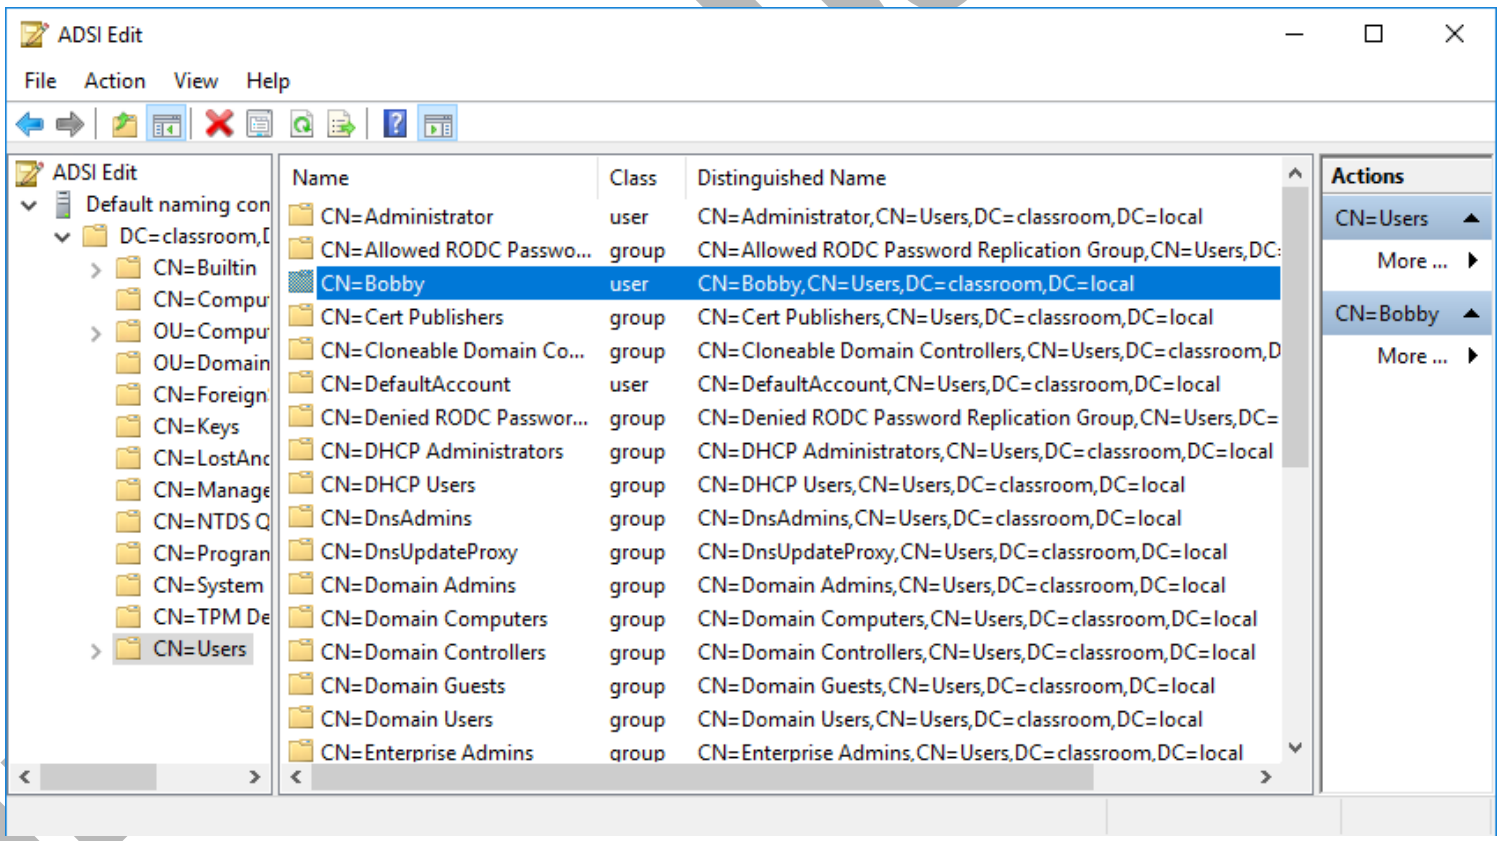
In Linux, local user account names are stored in /etc/passwd . When a user logs in to a local interactive shell, the password is checked against a hash stored in /etc/shadow . Interactive login over a network is typically accomplished using Secure Shell (SSH). With SSH, the user can be authenticated using cryptographic keys instead of a password.

A pluggable authentication module (PAM) is a package for enabling different authentication providers, such as smart-card log-in. The PAM framework can also be used to implement authentication to network directory services.

Directory Services

A directory service stores information about users, computers, security groups/roles, and services. Each object in the directory has a number of attributes. The directory schema describes the types of attributes, what information they contain, and whether they are required or optional. In order for products from different vendors to be interoperable, most directory services are based on the Lightweight Directory Access Protocol (LDAP) , which was developed from a standard called X.500.

Within an X.500-like directory, a distinguished name (DN) is a collection of attributes that define a unique identifier for any given resource. A distinguished name is made up of attribute-value pairs separated by commas. The most specific attribute is listed first, and successive attributes become progressively broader. This most specific attribute is the relative distinguished name, as it uniquely identifies the object within the context of successive (parent) attribute values.



Browsing objects in an Active Directory LDAP schema. (Screenshot used with permission from Microsoft.)

Some of the attributes commonly used include common name (CN), organizational unit (OU), organization (O), country (C), and domain component (DC).

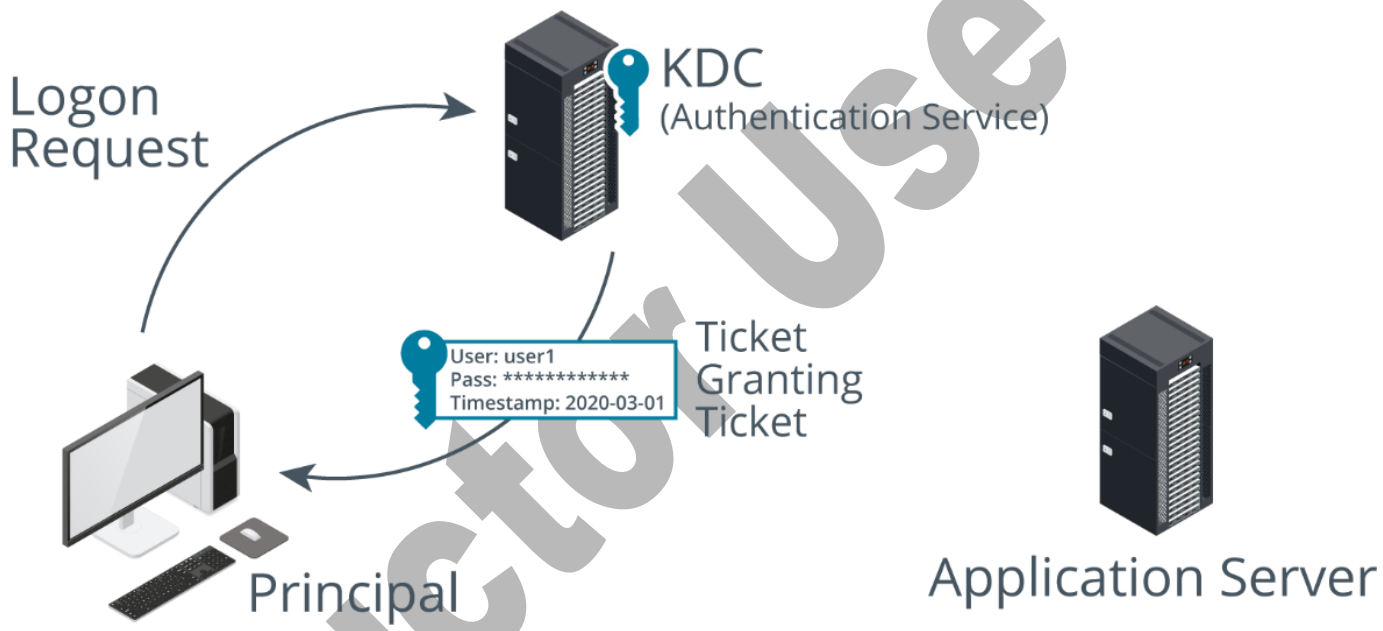
For example, the distinguished name of a web server operated by Widget in the UK might be the following:

CN=WIDGETWEB, OU=Marketing, O=Widget, C=UK, DC=widget, DC=foo

Single Sign-on Authentication

A single sign-on (SSO) system allows the user to authenticate once and then receive authorizations on compatible application servers without having to enter credentials again.

Kerberos is a single sign-on network authentication and authorization protocol used on many networks, notably as implemented by Microsoft's Active Directory (AD) service. Kerberos was named after the three-headed guard dog of Hades (Cerberus) because it consists of three parts. Clients request services from application servers, which rely on an intermediary—a key distribution center (KDC) —to vouch for their identity. There are two services that make up a KDC: the Authentication Service and the Ticket Granting Service.



Kerberos Authentication Service. (Images © 123RF.com.)

Kerberos can authenticate human users and application services. These are collectively referred to as *principals* . Using authentication to a Windows domain as an example, the first step in Kerberos SSO is to authenticate with a KDC server implemented as a domain controller.

- The principal sends the authentication service (AS) a request for a Ticket Granting Ticket (TGT) . This is composed by encrypting the date and time on the local computer with the user's password hash as the key.

The password hash itself is not transmitted over the network. Although we refer to passwords for simplicity, the system can use other authenticators, such as smart card login. The AS checks that the user account is present, that it can decode the request by matching the user's password hash with the one in the Active Directory database, and that the request has not expired. If the request is valid, the AS responds with the following data:

- **Ticket Granting Ticket (TGT)** — contains information about the client (name and IP address) plus a time stamp and validity period. This is encrypted using the KDC's secret key.

- **TGS session key** — communicates between the client and the Ticket Granting Service (TGS). This is encrypted using a hash of the user's password.

The TGT is an example of a logical token. All the TGT does is identify who you are and confirm that you have been authenticated—it does not provide you with access to any domain resources.

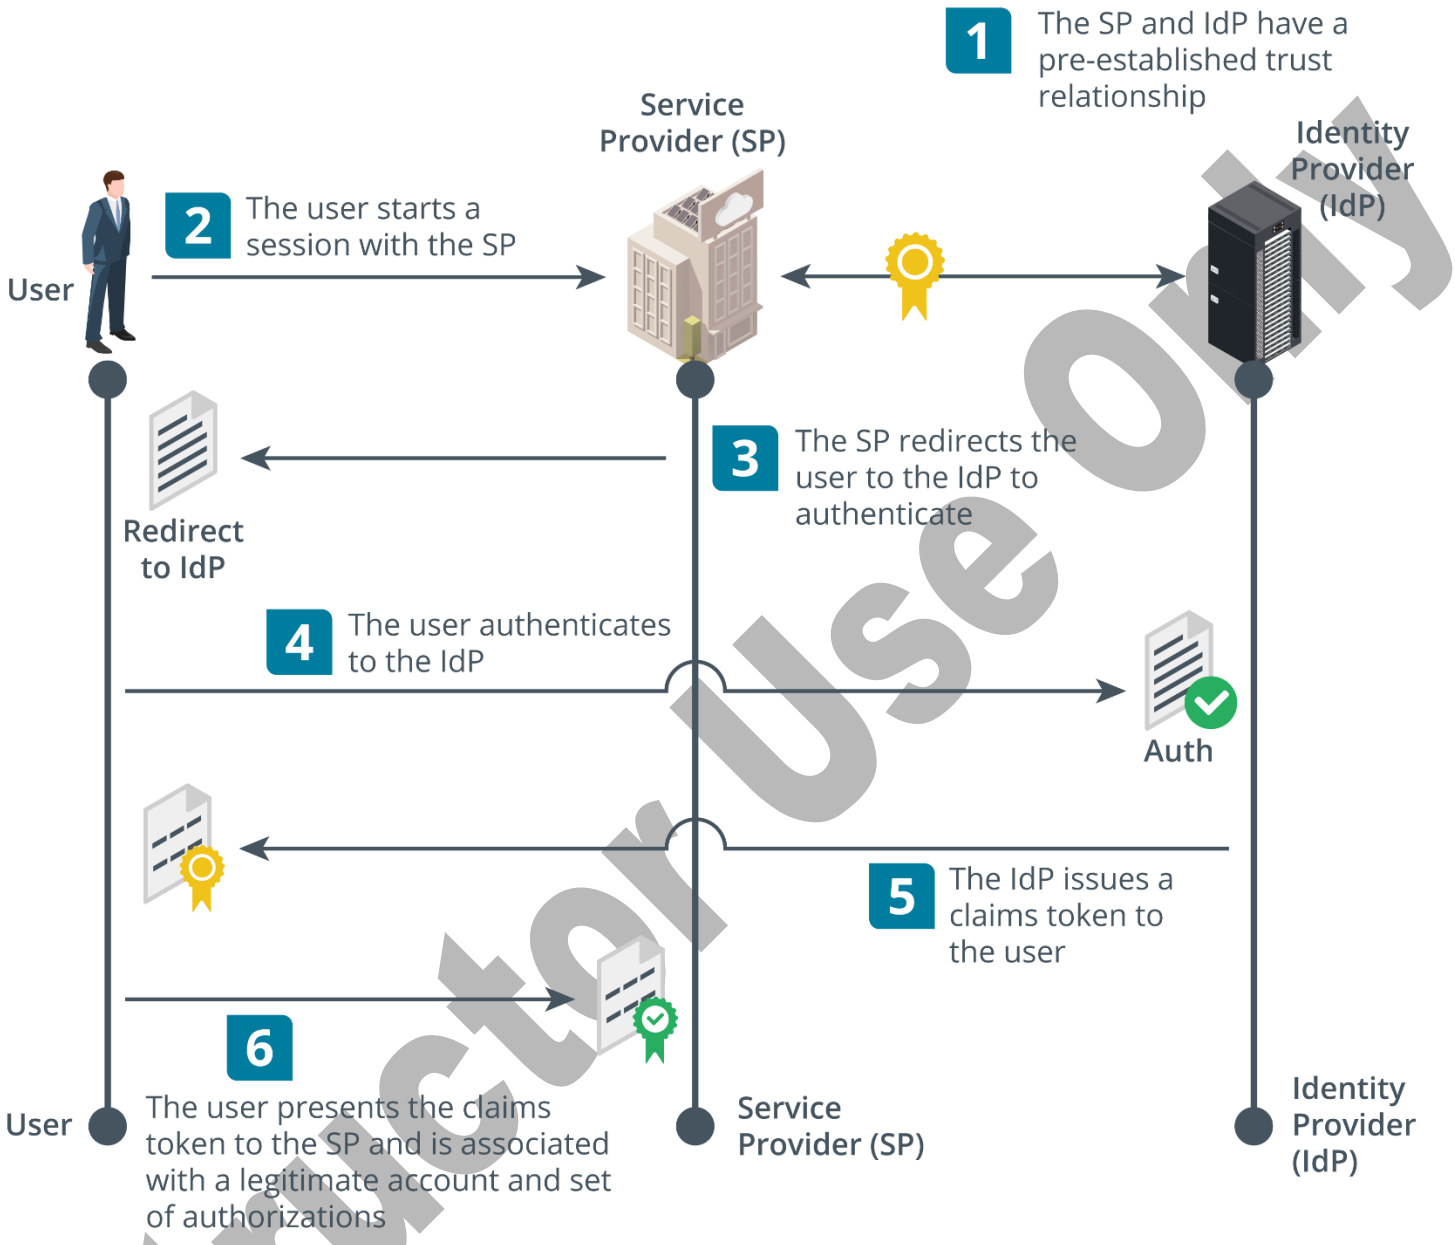
Federation

Federation is the notion that a network needs to be accessible to more than just a well-defined group of employees. In business, a company might need to make parts of its network open to partners, suppliers, and customers. The company can manage its employee accounts easily enough. Managing accounts for each supplier or customer internally may be more difficult. Federation means the company trusts accounts created and managed by a different network. As another example, in the consumer world, a user might want to use both Google Workspace and Twitter. If Google and Twitter establish a federated network for the purpose of authentication and authorization, then the user can log on to Twitter using their Google credentials or vice versa.

An on-premises network can use technologies such as LDAP and Kerberos, very often implemented as a Windows Active Directory network, because the administration of accounts and devices can be centralized. When implementing federation, authentication and authorization design comes with more constraints and additional requirements to ensure interoperability between different platforms. Web applications might not support Kerberos, while third-party networks might not support direct federation with Active Directory/LDAP. The design for these cloud networks likely requires the use of other standard protocols or frameworks for interoperability between web applications.

These interoperable federation protocols use claims-based identity. While the technical implementation and terminology are different, the overall model is similar to that of Kerberos SSO:

- The principal attempts to access a service provider (SP). The service provider redirects the principal to an identity provider (IdP) to authenticate.
- The principal authenticates with the identity provider and obtains a claim in the form of some sort of token or document signed by the IdP.
- The principal presents the claim to the service provider. The SP can validate that the IdP has signed the claim because of its trust relationship with the IdP.
- The service provider can now connect the authenticated principal to its own accounts database to determine its permissions and other attributes. It may be able to query attributes of the user account profile held by the IdP if the principal has authorized this type of access.



Federated identity management overview. (Images © 123RF.com.)

A federated network or cloud needs specific protocols and technologies to implement user identity assertions and transmit claims between the principal, the relying party, and the identity provider. Security Assertion Markup Language (SAML) is one such solution. SAML assertions (claims) are written in eXtensible Markup Language (XML). Communications are established using HTTP/HTTPS and the Simple Object Access Protocol (SOAP) . The secure tokens are signed using the XML signature specification. The use of a digital signature allows the relying party to trust the identity provider.

An example of a SAML implementation is Amazon Web Services (AWS), which functions as a SAML service provider. This allows companies using AWS to develop cloud applications to manage their customers' user identities and provide them with permissions on AWS without having to create accounts for them on AWS directly.

Open Authorization

Many public clouds use application programming interfaces (APIs) based on Representational State Transfer (REST) rather than SOAP. These are called RESTful APIs. Where SOAP is a tightly specified protocol, REST is a looser architectural framework. This allows the service provider more choice over implementation elements. Compared to SOAP and SAML, there is better support for mobile apps.

Authentication and authorization for a RESTful API are often implemented using the Open Authorization (OAuth) protocol. OAuth is designed to facilitate the sharing of information (resources) within a user profile between sites. The user creates a password-protected account at an identity provider (IdP). The user can link that identity to an OAuth consumer site without giving the password to the consumer site. A user (resource owner) can grant an OAuth client authorization to access some part of their account. A client in this context is an app or consumer site.

The user account is hosted by one or more resource servers. A resource server is called an API server because it hosts the functions that allow OAuth clients (consumer sites and mobile apps) to access user attributes. An authorization server processes authorization requests. A single authorization server can manage multiple resource servers; equally, the resource and authorization server could be the same server instance.

The client app or service must be registered with the authorization server. As part of this process, the client registers a redirect URL, which is the endpoint that will process authorization tokens. Registration also provides the client with an ID and a secret. The ID can be publicly exposed, but the secret must be kept confidential between the client and the authorization server. When the client application requests authorization, the user approves the authorization server to grant the request using an appropriate method. OAuth supports several grant types—or flows—for use in different contexts, such as server to server or mobile app to server. Depending on the flow type, the client will end up with an access token validated by the authorization server. The client presents the access token to the resource server, which then accepts the request for the resource if the token is valid.

OAuth uses the JavaScript Object Notation (JSON) Web Token (JWT) format for claims data. JWTs can be passed as Base64-encoded strings in URLs and HTTP headers and can be digitally signed for authentication and integrity.

4.2.5 Biometrics and Authentication Technologies (Lesson Video)

Transcript:

In this lesson, we'll look at biometrics and some of the other technologies used for multifactor authentication. Remember, authentication is the process of verifying a claimed identity. And to verify an identity, we need a unique piece of information that could only come from one person.

Biometric authentication has come a long way. You're probably familiar with fingerprint and retina scans, but did you know that people can also be identified by their iris, facial structure, and even by their gait when they walk?
Biometric authentication requires capturing and storing a unique physical attribute in a biometric system. The initial capture is called enrollment. Subsequent authentication attempts are then tested against the stored biometric template.
A few key parameters can determine whether an attribute is viable.
First, the physical attribute should be universal â€“ something that everyone has. Second, the attribute should be unique. It should be measurable and so distinctive that it can be used to tell people apart. Third, the attribute should be permanent â€“ in other words, it should hold up to aging. For example, a person's face might change considerably over time, but their fingerprint or retina will stay the same.
Fourth, the attribute must be collectable. In other words, how easy is it to acquire this measurable attribute? If collecting the measurement is difficult or invasive, it probably won't work. Lastly, the attribute must be difficult to duplicate. For example, if the attribute is the person's voice, it might be possible to evade the system using an audio recording. But if the attribute is the person's retina, then it's much more difficult to circumvent.
If errors do occur, they can be labeled as a false positive or a false negative. A false positive occurs when the biometric system returns a positive match and identifies an unauthorized user as a legitimate user.
A false negative occurs when the biometric system returns a negative match when a legitimate user tries to authenticate.
Now let's look at some other technologies that are used for authentication. You've probably already used a lot of these methods.
To provide an extra layer of security for their employees, some organizations use authenticator applications for their remote employees. An authenticator app, typically installed on a smartphone, provides a 6- to 8-digit code. Every 30 seconds, that code changes. The employee enter their username and password along with the code from the authenticator app, providing additional verification that you are who you say you are.
A similar method that you may have used is a one-time password.
Some banks use this method to allow ATM withdrawals without using a debit card or to let customers access their accounts from the internet.
An application or token creates a one-time password. This password will only work for a single login. After that, the password expires. The password also expires if it isn't used withing a short period of time.
These one-time passwords can be sent to the users several ways.
For example, the one-time password can be sent using the Short Message Service, or SMS. When this option is selected, an SMS message with a one-time code or password is sent to your previously verified phone number. This code can then be used to verify your identify and complete your login.
Similarly, if you chose to receive your code through the phone, you'll get a phone call and an automated voice will provide you with a one-time code or password.
Push notification authentication can also be used to grant access to an account. For example, when you log in to your account, you'll enter your username, but instead of a password, you receive an access request notification on your mobile device. You can then view the authentication details and approve or deny access, typically with a simple press of a button.
One advantage of using this authentication method is that you don't have to remember passwords. However, this method only works with the services provided by a specific company. As a result, there are a limited number of applications that integrate with their services. This makes them unavailable to organizations that use enterprise-level and proprietary solutions.
That's it for this lesson. In this lesson, we looked at biometric systems and several other authentication technologies used for multifactor authentication.

4.2.6 Use a Biometric Scanner (Demo Video)

Transcript:

In this demonstration, we're going to configure biometric authentication systems for Windows. I'm going to use the biometric scanner that's built into the hardware of this laptop, a fingerprint scanner. In order for a computer to use biometrics to authenticate, software to support the login must be on the system. This system has software to handle our fingerprint reader. Each biometric device will need to be supported on the system you wish to use. Based on the type of device you use, you'll configure the operating system to authenticate using the biometrics it offers—your fingerprint, your face, or something else.

Before authenticating with biometrics, you'll need to register with the device. For example, for a fingerprint reader such as the one I'm using, I'll need to register my fingerprint with the device by having it scan the finger a few times. Once registered, that same fingerprint can then be used to authenticate. Authentication happens when the registered biometric, our fingerprint, is compared to the fingerprint that's being scanned on the device. If they match, authentication is granted. Keep in mind that with fingerprints, if your hands are wet or dirty, it will be harder for your biometric system to authenticate you, and your fingerprint will be less likely to match with your previous scan.
Let's demonstrate how to register a fingerprint with this system. I'll search for fingerprint, then click on the Set up fingerprint sign-in option. This opens the Sign-in options Settings page. I'll click on Fingerprint recognition (Windows Hello), then click on Set up.
We're prompted to enter our PIN, a backup authentication method in case the fingerprint isn't available. I've already set up the PIN. But if the PIN hadn't been defined, I would be prompted to configure it. Now, it's asking me to put my finger on the scanner. Then it'll ask me to pick it up and set it down on the reader multiple times while it takes a detailed capture of the fingerprint. This may take a few moments to complete. Now, our configuration is done, and the fingerprint scanner is ready to be used to log on to the system. You also have the option to Add another finger. I only need the one, so that's all I'll add.
And that's all for this demonstration. We talked about how to register your fingerprint with the biometric authentication system.

4.2.7 Use Single Sign-on (Demo Video)

Transcript:

In this demo, we're going to look at single sign-on, or SSO. Now, before we begin, I want to point out that you've probably used single sign-on without even knowing it. In fact, if you have a Gmail or Facebook account, then you've definitely used single sign-on. And if you've ever logged into a Windows domain on a computer, you've used single sign-on there too. Single sign-on is an authentication method that requires you to log in only once to have access to a wide range of services. In a domain, these services include things like file servers and print servers. When you log in, you can access the file server without providing authentication credentials again. It's really nice.

Now, we aren't going to see single sign-on with a domain in this demo. Instead, we're going to look at single sign-on with Google internet services.
Let's start by logging in to a google account. You're probably familiar with Google's email service, Gmail. Let's go to gmail.com and enter our login information. We've logged into Gmail. Because we logged into our single Gmail account, now we have access to all of these Googles services without needing to provide authentication credentials again. There are a lot of them. All of these services fall under the single sign-on of Google.
For example, let's click the YouTube icon, which will take us to YouTube's page. In the top right here, notice that we're automatically signed in. We didn't need to type our username or password. This is because YouTube is connected with Google, which uses a single sign-on service.
The same is true for other Google services. If we go back and click on Google Drive, we have access to that as well. No need to log in.
Let's search LinkedIn in Google. Click Join Now. Notice here, instead of creating an account with LinkedIn directly, we can create an account with Google. This creates a single sign-on link of sorts between LinkedIn and Google that makes it so when we're logged in on Google, we're also logged in on LinkedIn.
Let's try another. Let's go to wordpress.com. Click Log In and look down here. Instead of creating an account, we can link our Google account by clicking Continue with Google. When we do, we're asked which account to link.

We only have one, so I'll click on it. And now, after we wait a minute or two, an account will be created, and we're logged in to the service without needing to provide our password. Again, this is because of the single sign-on functionality that's been implemented between WordPress and Google.
Now, because everything is linked to our Google account, when we log out of it, we're also logged out of those services. Let's do that. We'll log out of Gmail. The page will refresh, and we're asked to log in. So, what happened with Wordpress? Let's go back and look. I'll type â€˜wordpress.com' and press Enter.
Back on WordPress, we're still logged in. This is probably because of how the session cookies are handled. We know we're logged out of Google, so let's log out of WordPress. I'm taken back to the logon page. Click Sign in. We're taken back to the Log in to your account page. I'll click Sign in with Google. Notice my account info here. My password is automatically populated. I'll click Next.
After just a few seconds, I'm logged back into WordPress. Now, guess what else happened? We were actually logging into our Google account again. If I jump back over to my Gmail account, you can see that I was logged back into there, too.
As you can see, single sign-on can be extremely useful and convenient. However, as we know all too well, convenience comes with risk. For example, using single sign-on presents the risk that if someone were to compromise a single account, they could potentially have access to any service that has been linked to that account. One thing that can protect against this is multi-factor authentication, such as requiring a one-time key to access different services.
That's it for this demonstration. In this demo, we looked at single sign-on. We looked at a few different single sign-on features and how a single account can be used to access multiple services.

4.2.8 Biometrics and Authentication Technologies Facts

Biometric authentication is based on a unique physical attribute or characteristic. This type of authentication requires capturing and storing a unique physical attribute with a biometric system.

This lesson covers the following topics:

- Biometric parameters
- Biometric authentication
- Common collection methods

Biometric parameters

For biometric authentication to be a viable security mechanism, it is important to consider the following parameters:

Parameter	Description
Universal	Does each person have the physical attribute being measured?
Unique	Is the physical attribute distinctive enough that it can be used to distinguish between individuals?
Permanent	How well does the specified attribute hold up to aging?
Collectible	How easy is it to acquire this measurable attribute?
Circumvention	Can the attribute be easily circumvented?
Accuracy	Are the results accurate? Accuracy is extremely critical in a biometric system.

Biometric Authentication

The first step in setting up biometric authentication is enrollment:

- A sensor module acquires the biometric sample from the target.
- A feature extraction module creates a template. The template is a mathematical representation of the parts of the sample that uniquely identify the target.

When the user wants to access a resource, they are re-scanned, and the scan is compared to the template. If they match to within a defined degree of tolerance, access is granted.

Biometric authentication can be challenging to implement. The efficacy rate of biometric pattern acquisition and matching and suitability as an authentication mechanism can be evaluated using the following metrics and factors:

- **False rejection rate (FRR)** — is where a legitimate user is not recognized. This is also referred to as a Type I error or false non-match rate (FNMR). FRR is measured as a percentage.
- **False acceptance rate (FAR)** — is where an interloper is accepted (Type II error or false match rate [FMR]). FAR is measured as a percentage.

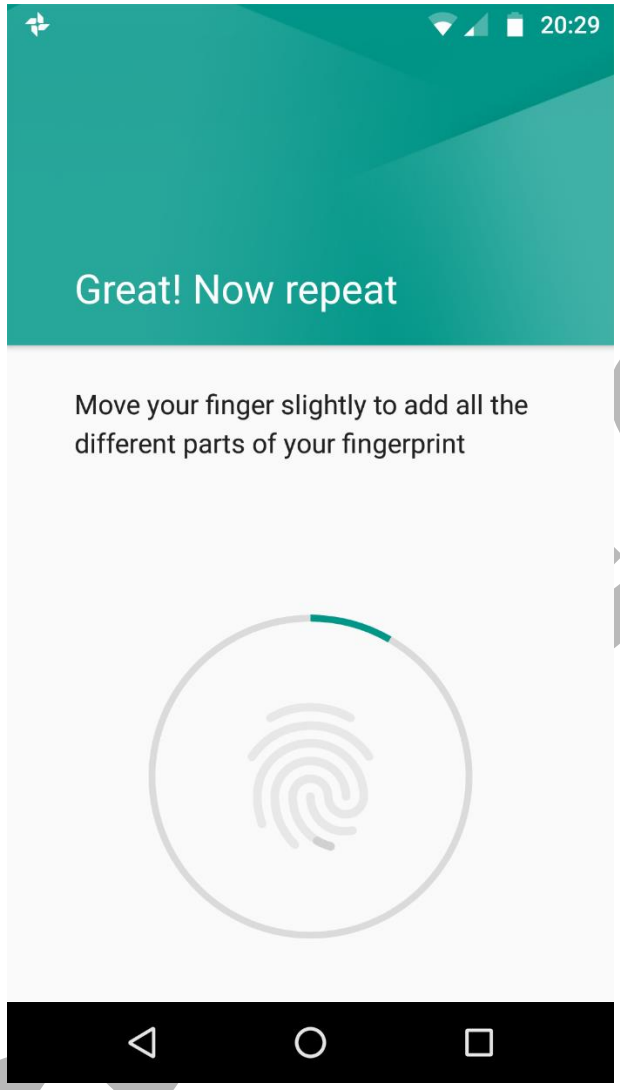
False rejection causes inconvenience to users, but false acceptance can lead to security breaches, which is usually considered the most important metric.

- **Crossover Error Rate (CER)** — the point at which FRR and FAR meet. The lower the CER, the more efficient and reliable the technology.

Errors are reduced over time by tuning the system. This is typically accomplished by adjusting the sensitivity of the system until CER is reached.

- **Throughput (speed)** — the time required to create a template for each user and the time required to authenticate. This is a major consideration for high-traffic access points, such as airports or railway stations.
- **Failure to Enroll Rate (FER)** — are incidents in which a template cannot be created and matched for a user during enrollment.
- **Cost/Implementation** — some scanner types are more expensive, whereas others are not easy to incorporate on mobile devices.
- Users can find it intrusive and threatening to privacy.
- The technology can be discriminatory or inaccessible to those with disabilities.

Fingerprint recognition is the most widely implemented biometric authentication method. The technology required for scanning and recording fingerprints is relatively inexpensive, and the process is quite straightforward. A fingerprint sensor is usually implemented as a small capacitive cell or optical camera that can detect the unique pattern of ridges making up the pattern. The technology is also nonintrusive and relatively simple to use, although moisture or dirt can prevent readings.



Configuring fingerprint recognition on an Android ™ smartphone. Android is a trademark of Google LLC.

Facial recognition records multiple indicators about the size and shape of the face, like the distance between the eyes or the width and length of the nose. The scan usually uses optical and infrared cameras or sensors to defeat spoofing attempts that substitute a photo for a real face.

Common Collection Methods

Biometric information can be collected for each of the following:

Method	Description
Fingerprints	Fingerprints are made up of patterns of ridges and valleys. Fingerprint scanners analyze these patterns and convert them into a numerical format that can be stored for future comparison.
Retina	The retina is the back portion of the eye sensitive to light. Numerous capillaries move blood to the retina, and these capillaries create a unique pattern. A retinal scanner shines infrared light into an

Method	Description
	eye and measures the amount of reflection. The vessels in the retina absorb infrared light so that the reflection pattern can be stored for future identification.
Iris	The iris is the colorful portion of the eye around the pupil. Infrared light lights up the iris, and the scanner captures images of its unique patterns.
Facial	Facial scanning creates a map of 80 points on an individual's face. The distances measured on this map can be used to identify the person in the future. Measurements could include the distance between the eyes, the nose's shape, the cheekbones' size, etc.
Voice	Voice recognition systems analyze a person's voice for pitch, intensity, and cadence. These systems can be text-dependent or text-independent. Text-dependent authentication requires a specific phrase to be spoken. This could be a pre-determined phrase, or it could be randomly generated. Text-independent authentication uses any speech content.
Vein	Vein recognition scanners use infrared light to determine the vein pattern in your palm. Like a fingerprint, this pattern differs from person to person and does not change. The scanner converts the collected data into a code that is encrypted and assigned to you. The benefits of vein biometrics are: • Veins are internal, so they cannot be altered or covered as easily as hands or a face could be. • More data points can be collected because a palm is larger than an eye or a finger. This provides a higher rate of accuracy. • Internal veins are harder to replicate and can only be captured in proximity.
Gait	Gait recognition analyzes the way that people walk. Each person has a unique way of walking. Several factors determine your gait, including: • Height, weight, and body. • Age. • Health (diseases or disorders). • Personality and emotions. When analyzing gait, the following are measured: • Stride. • Step. • Speed. • Hip and foot angle. • Cadence. Data is gathered using sensors, cameras, or wearable devices. The gait recognition system creates a digital signature that can be stored or compared to existing data. As with most biometric systems, gait recognition systems are still relatively new and should not be used as a stand-alone identification method.

4.2.9 Practice Questions (Section Quiz)

q_authent_biometrics_secp8

The IT security team at a large company is implementing more robust authentication measures to safeguard sensitive data and systems. The team is exploring multi-factor authentication (MFA) options to bolster security. The company deals with highly confidential information and requires a robust solution.

The team has narrowed the choices and is evaluating which aligns BEST with their security needs.

Which multi-factor authentication method utilizes unique physical characteristics of individuals to verify their identity?

Answers:

- ***Biometrics**
- SMS-based one-time passwords (OTP)
- Smart cards
- Passwords and PINs

Explanation:

In biometrics, unique physical characteristics or behavioral traits, such as fingerprints or facial recognition, actively verify a user's identity.

Short message service (SMS)-based one-time passwords (OTPs) actively send temporary codes to users' mobile phones via SMS. While an OTP adds an extra layer of security, it does not actively utilize physical or behavioral traits for verification, making it less secure than biometrics.

Smart cards provide an additional layer of authentication by requiring users to insert or tap a physical card, but they do not involve unique physical or behavioral characteristics like biometrics.

Passwords and personal identification numbers (PINs) actively represent single-factor authentication methods that rely solely on something the user knows.

q_authent_have_secp8

Which of the following are examples of *something you have* authentication controls? (Select two.)

Answers:

- PIN
- Cognitive question
- ***Photo ID**
- ***Smart card**
- Voice recognition
- Handwriting analysis

Explanation:

Something you have authentication controls include physical items that you have on your possession, such as a smart card, photo ID, token device, or swipe card.

Something you know authentication requires you to provide a password, PIN, pass phrase, or the answer to a cognitive question (such as your mother's maiden name).

Something you are authentication uses a biometric system, such as a fingerprint, retina scan, voice recognition, keyboard, or writing recognition.

q_authent_identity_secp8

Which of the following identification and authentication factors are often well known or easily discovered by others on the same network or system?

Answers:

- ***Username**
- Password
- PGP secret key
- Biometric reference profile

Explanation:

The username is typically the least protected identification and authentication factor. Therefore, usernames are often well known or easy to discover, especially by others on the same network or system. The key to maintaining a secure environment is to keep authentication factors secret. Often, usernames are constructed using a standard naming convention, such as first and middle initials plus the full last name, or the first name and last name separated by a period. If these simple construction conventions are known, building usernames from an employee list is very simple.

Passwords, your PGP secret key, and your biometric reference profile are less likely to be well known or easy to discover.

q_authent_know_01_secp8

Which of the following is a password that relates to things that people know, such as a mother's maiden name or a pet's name?

Answers:

- ***Cognitive**
- Dynamic
- One-time
- Passphrase

Explanation:

Cognitive passwords relate to things that people know, such as a mother's maiden name or a pet's name.

Dynamic passwords change upon each consecutive login.

One-time passwords are only valid for a single use.

A passphrase is a password long enough to be a phrase.

q_authent_know_02_secp8

What type of password is *maryhadalittlelamb?*

Answers:

- ***Passphrase**
- Cognitive
- Static
- Composition

Explanation:

A passphrase is a password long enough to be a phrase, such as *maryhadalittlelamb*.

Cognitive passwords relate to things that people know, such as a mother's maiden name or a pet's name,

A static password is created by a user and overseen by an administrator.

Composition passwords are created by the system and are usually two or more unrelated words divided by symbols on the keyboard.

q_authent_know_03_secp8

Which of the following is the MOST common form of authentication?

Answers:

- Photo ID
- Fingerprint
- Digital certificate on a smart card
- ***Password**

Explanation:

Passwords are the most common form of authentication. Most secure systems require only a username and password to provide users with access to the computing environment. Many forms of online intrusion attacks focus on stealing passwords. This makes using strong passwords very important. Without a strong password policy and properly trained users, the reliability of your security system is greatly diminished.

Photo ID, fingerprint, and digital certificate on a smart card are not the most common forms of authentication.

q_authent_multifactor_secp8

Match the authentication factor types on the left with the appropriate authentication factor on the right. Each authentication factor type may be used more than once.

Answers:

- Something you know
- Something you have
- Something you are
- Somewhere you are
- Something you do

Explanation:

Something you know authentication requires you to provide a password or some other data that you know. This is the weakest type of authentication. Examples of something you know authentication controls include:

- Passwords, codes, or IDs
- PINs
- Passphrases (long multi-word passwords)

Something you have (also called token-based authentication) is authentication based on something users have in their possession. Examples of something you have controls include:

- Swipe cards
- Photo IDs
- Smart cards
- Hardware tokens

Something you are authentication uses a biometric system. A biometric system attempts to identify a person based on metrics or a mathematical representation of the subject's biological attribute. Biometric systems are the most expensive and least accepted system type, but are generally considered the most secure form of authentication. Common attributes used for biometric systems include:

- Fingerprints
- Hand topology (side view) or geometry (top-down view)
- Palm scans
- Retina scans
- Iris scans
- Facial scans
- Voice recognition

Somewhere you are authentication (also known as geolocation) is a supplementary authentication factor that uses physical location to verify a user's identity. Examples of implementations include:

- An account is locked unless the user has passed through the building's entrance using an ID card.
- If the user is within RFID range of the workstation, authentication requests are allowed.
- GPS or Wi-Fi triangulation location data is used to determine a device's location. If the user and the device are in a specified location, authentication requests are allowed. If not, the device is locked.

Something you do is a supplementary authentication factor that requires an action to verify a user's identity. Example implementations include:

- Analyzing a user's handwriting sample against a baseline sample before allowing authentication.
- Analyzing a user's typing behaviors against a baseline sample before allowing authentication.

q_authent_passwordless_01_secp8

The IT department at a medium-sized company is exploring ways to enhance its authentication methods to improve security. They want to choose an authentication approach that balances security and user convenience.

Which authentication method eliminates the need for passwords and provides a secure way of verifying a user's identity based on the device's hardware or software characteristics?

Answers:

- ***Passwordless authentication**
- Attestation
- Multi-factor authentication
- Biometric authentication

Explanation:

Passwordless authentication eliminates traditional passwords and relies on other factors such as biometrics, security keys, or mobile push notifications for user verification.

Attestation involves verifying the integrity and authenticity of a device's hardware or software. While it can enhance overall security, it is not a passwordless authentication method.

Multi-factor authentication (MFA) involves using multiple authentication factors, which can include something the user knows (like a password) along with something they have or are (like a fingerprint). While it can enhance security, it still involves using passwords in some cases.

Biometric authentication uses physical characteristics such as fingerprints or facial recognition to verify a user's identity.

q_authent_passwordless_02_secp8

A leading online retail company wants to improve user experience and security for its customers. The security team aims to eliminate the need for users to remember or input complex passwords, reducing the risk of password breaches.

Instead, they propose a solution where users can access their accounts seamlessly through a secure link sent to their verified email or via a push notification on a trusted device. This approach should not involve traditional passwords, fingerprint scans, or multiple validation steps.

Which authentication method is the security team planning to implement for users?

Answers:

- ***Passwordless authentication**
- Attestation
- Multi-factor authentication
- Biometric authentication

Explanation:

Passwordless authentication eliminates traditional passwords and relies on other factors like biometrics, security keys, or mobile push notifications for user verification.

Attestation involves verifying the integrity and authenticity of a device's hardware or software. While it can enhance overall security, it is not a passwordless authentication method.

Multi-factor authentication (MFA) involves using multiple authentication factors, which can include something users know (like a password) along with something they have or are (like a fingerprint). While it can enhance security, it still involves using passwords in some cases.

Biometric authentication uses physical characteristics like fingerprints or facial recognition to verify a user's identity.

q_authent_security_keys_01_secp8

The IT security team at a large tech company is strengthening its authentication methods to protect sensitive company data and systems. The team considered implementing various security measures and understood that each authentication method has distinct features and benefits.

However, they must choose the MOST suitable option that aligns with the organization's security requirements and user convenience.

Which authentication method utilizes a physical device or software to generate secure, unique codes and offers convenience and strong security?

Answers:

- ***Security keys**
- Hard authentication tokens
- Biometric authentication
- Soft authentication tokens

Explanation:

Security keys are authentication devices, either physical hardware or software-based, that generate secure, unique codes for authentication purposes.

Hard authentication tokens are physical devices that generate one-time passwords (OTPs) or passcodes used for authentication. The codes are unique and time-based, so they reduce the risk of unauthorized access.

Biometric authentication relies on unique biological characteristics such as fingerprints, iris patterns, or facial recognition to verify a user's identity. While it offers convenience, it is not explicitly related to security keys.

Soft authentication tokens are software-based and generate one-time passwords (OTPs) or passcodes on a user's device.

q_authent_security_keys_02_secp8

The cybersecurity expert at a technology firm recommends adding another layer of protection to employee accounts. The expert suggests a physical device that users can insert or tap on compatible systems to verify their identity alongside a password.

The proposed solution should use something other than biometric data, produce time-sensitive codes, or be an app or software on personal devices.

Which authentication method is the cybersecurity expert recommending for the employees?

Answers:

- ***Security keys**
- Hard authentication tokens
- Biometric authentication
- Soft authentication tokens

Explanation:

Security keys are authentication devices, either physical hardware or software-based, that generate secure, unique codes for authentication purposes.

Hard authentication tokens are physical devices that generate one-time passwords (OTPs) or passcodes used for authentication. The codes are unique and time-based, so they reduce the risk of unauthorized access.

Biometric authentication relies on unique biological characteristics such as fingerprints, iris patterns, or facial recognition to verify a user's identity. While it offers convenience, it is not explicitly related to security keys.

Soft authentication tokens are software-based and generate one-time passwords (OTPs) or passcodes on a user's device.

q_authent_smart_secp8

A smart card can be used to store all but which of the following items?

Answers:

- Digital signature
- ***Biometric template original**
- Cryptography keys
- Identification codes

Explanation:

A smart card cannot store biometric template originals, as those are physical components of the human body.

A smart card can store digital signatures, cryptography keys, and identification codes.

q_authent_you_are_01_secp8

A technician is assisting a group of new employees with setting up multi-factor authentication.

What philosophy incorporates the use of facial scans or fingerprints to demonstrate authentication?

Answers:

- ***Something you are**
- Somewhere you are
- Something you know
- Something you have

Explanation:

Something you are refers to a biometric or inherence factor. A biometric factor uses physiological identifiers, such as a fingerprint or facial scan, or behavioral identifiers, such as how someone moves (gait).

Somewhere you are means the system applies a location-based factor to an authentication decision. Location-based authentication measures some statistics about where you are.

Something you know means the information used for authentication is from something one can recall, such as a passphrase or username/password combination.

Something you have means the account holder possesses something that no one else does, such as a smart card, key fob, or smartphone that can generate or receive a cryptographic token.

q_authent_you_are_02_secp8

After finding a corporate phone unattended in a local mall, an organization decides to enhance its multi-factor authentication (MFA) procedures.

What MFA philosophy applies a location-based factor for authentication?

Answers:

- ***Somewhere you are**
- Something you know
- Something you have
- Something you are

Explanation:

Somewhere you are means the system applies a location-based factor to an authentication decision. Location-based authentication measures some statistics about where you are.

Something you know means the information used for authentication is from something one can recall, such as a passphrase or username/password combination.

Something you have means the account holder possesses something that no one else does, such as a smart card, key fob, or smartphone that can generate or receive a cryptographic token.

Something you are refers to a biometric or inherence factor. A biometric factor uses physiological identifiers, such as a fingerprint or facial scan, or behavioral identifiers, such as how someone moves (gait).

q_authent_methods_claims-based_sec8

You are a security architect for a large organization that uses various cloud services. The organization wants to implement a system that allows users to authenticate once and then access multiple applications, with the system providing information about the user to the applications.

The system should be able to work across multiple platforms and authentication systems.

Which solution would you recommend?

Answers:

- Local authentication
- ***Claims-based identity**
- Network authentication
- Password-based authentication

Explanation:

Claims-based identity is the correct answer. In a claims-based identity system, an identity provider issues a token containing claims about the user (such as the user's name, role, or privileges) to the user's browser. The user's browser then presents this token to applications, which use the claims to decide what the user is allowed to do. This system can work across multiple platforms and authentication systems.

Local authentication is incorrect because local authentication is used to authenticate a user to a specific system or application. It does not provide a way for users to authenticate once and then access multiple applications.

Network authentication is incorrect because network authentication is used to authenticate a user to a network. It does not provide a way for users to authenticate once and then access multiple applications.

Password-based authentication is incorrect because password-based authentication is a method of authenticating a user based on something the user knows (their password). It does not provide a way for users to authenticate once and then access multiple applications.

q_authent_methods_dn_sec8

As a network administrator, you are tasked with creating a new entry in your company's LDAP directory. You need to ensure that the entry is uniquely identifiable and conforms to the structure of the directory.

Which of the following attributes would you use to accomplish this?

Answers:

- Common name
- Organizational unit (OU)
- ***Distinguished name (DN)**
- Domain component (DC)

Explanation:

Distinguished name (DN) is the correct answer. The distinguished name is a collection of attributes that define a unique identifier for any given resource in an LDAP directory. A DN is made up of attribute-value pairs, separated by commas. The most specific attribute is listed first, and successive attributes become progressively broader.

Common name (CN) is incorrect because the common name is just one attribute of an LDAP entry and is not sufficient to uniquely identify an entry in the directory.

Organizational unit (OU) is incorrect because the organizational unit is just one attribute of an LDAP entry and is not sufficient to uniquely identify an entry in the directory.

Domain component (DC) is incorrect because the domain component is just one attribute of an LDAP entry and is not sufficient to uniquely identify an entry in the directory.

q_authent_methods_federation_01_sec8

Your financial planning company is forming a partnership with a real estate property management company. One of the requirements is that your company open up its directory services to the property management company to create and access user accounts.

Which of the following authentication methods will you be implementing?

Answers:

- ***Federation**
- Single sign-on
- Attestation

- Directory services

Explanation:

In this scenario, you would be implementing a federation authentication method. Federation is the notion that a network needs to be accessible to more than just a well-defined group of employees, such as trusting user accounts created and managed by a different network.

Single sign-on is an authentication process that allows users to access multiple systems, applications, or websites using only a single set of credentials. With SSO, a user authenticates once using designated credentials and can access different resources seamlessly.

Attestation is a protocol used to prove that software can be trusted. It tells the remote user that the application or OS software is legitimate and certified.

Directory services implement single sign-on for resources on the network.

q_authent_methods_federation_02_sec8

You are a network administrator for a multinational corporation that uses various cloud services. The corporation has offices in multiple countries, each with their own local directories for managing accounts and rights.

The CEO wants to implement a system that allows these authorizations to be implemented across all offices and cloud services.

Which solution would you recommend?

Answers:

- Local directory
- Network directory
- ***Federation**
- Single sign-on authentication

Explanation:

Federation is the correct answer. Federation is a system that allows for the implementation of authorizations across different domains, such as multiple offices or cloud services. It uses a federated identity management solution to manage accounts and rights across these different domains.

Local directory is incorrect because a local directory is used to manage accounts and rights within a single office or location. It would not allow for authorizations to be implemented across multiple offices and cloud services.

Network directory is incorrect because a network directory, while it can manage accounts and rights across a network, would not allow for authorizations to be implemented across multiple offices and cloud services, especially if those services are from different vendors.

Single sign-on authentication is incorrect because while single sign-on authentication allows a user to authenticate once and receive authorizations for multiple services, it does not manage accounts and rights across multiple offices and cloud services.

q_authent_methods_kerberos_sec8

You are a network administrator for a large organization that uses a single sign-on (SSO) system for network authentication and authorization.

The organization has recently experienced a security breach, and in response, the CEO wants to implement a system that can authenticate both human users and application services, and that relies on an intermediary to vouch for their identity.

Which protocol would you recommend?

Answers:

- Secure Shell (SSH)
- Lightweight Directory Access Protocol (LDAP)
- Network Time Protocol (NTP)
- ***Kerberos**

Explanation:

Kerberos is the correct answer. Kerberos is a network authentication protocol that works on the basis of tickets to allow nodes communicating over a non-secure network to prove their identity to one another in a secure manner. It can authenticate human users and application services, and relies on a key distribution center to vouch for their identity, which is exactly what the CEO is asking for.

Secure Shell (SSH) is incorrect because SSH is a cryptographic network protocol for operating network services securely over an unsecured network, but it does not provide the intermediary authentication service that the CEO is asking for.

Lightweight Directory Access Protocol (LDAP) is incorrect because LDAP is a protocol used to access and maintain distributed directory information services, but it does not provide the intermediary authentication service that the CEO is asking for.

Network Time Protocol (NTP) is incorrect because NTP is used to synchronize the clocks of computers over a network, but it does not provide the intermediary authentication service that the CEO is asking for.

q_authent_methods_ldap_sec8

You are a network administrator for a large multinational corporation. The corporation has offices in multiple countries and uses various software products from different vendors.

The CEO wants to implement a system that stores information about users, computers, security groups/roles, and services, and allows for interoperability between different vendors' products.

Which directory service would you recommend?

Answers:

- Active Directory
- Novell Directory Services (NDS)
- ***Lightweight Directory Access Protocol (LDAP)**
- X.500

Explanation:

Lightweight Directory Access Protocol (LDAP) is the correct answer. LDAP is a protocol used to access network directory databases, which store information about authorized users and their privileges, as well as other organizational information. Most directory services, including those from different vendors, are based on LDAP, which allows for interoperability.

Active Directory is incorrect because while Active Directory is a directory service, it is a Microsoft product and may not offer the desired level of interoperability with products from different vendors.

Novell Directory Services (NDS) is incorrect because NDS, while a directory service, is a Novell product and may not offer the desired level of interoperability with products from different vendors.

X.500 is incorrect because while X.500 is a standard for directory services, it is not as widely used as LDAP and may not offer the desired level of interoperability with products from different vendors.

q_authent_methods_pam_sec8

You are a system administrator for a company that uses Linux servers. One of your tasks is to implement a new smart-card login system for all employees.

Which Linux authentication method would you use to accomplish this?

Answers:

- Local user account names stored in /etc/passwd
- Password checked against a hash stored in /etc/shadow
- Secure Shell (SSH)
- ***Pluggable Authentication Module (PAM)**

Explanation:

Pluggable Authentication Module (PAM) is the correct answer. PAM is a package for enabling different authentication providers, such as smart-card login. The PAM framework can also be used to implement authentication to network directory services. This would allow you to implement the new smart-card login system for all employees.

Local user account names stored in /etc/passwd is incorrect because this method is used for storing local user account names, not for implementing a smart-card login system.

Password checked against a hash stored in /etc/shadow is incorrect because this method is used for checking a user's password against a stored hash during login, not for implementing a smart-card login system.

Secure Shell (SSH) is incorrect because SSH is used for secure remote login and other secure network services over an insecure network, not for implementing a smart-card login system.

q_authent_methods_remote_sign-in_sec8

A company's IT department has received a request from an employee who is currently working from home. The employee is unable to access the company's internal resources from their home network.

As an IT professional, which type of Windows authentication would you recommend to resolve this issue?

Answers:

- Windows local sign-in

- Windows network sign-in
- ***Remote sign-in**
- Linux authentication

Explanation:

Remote sign-in is the correct answer. Use remote sign-in when the user's device is not directly connected to the local network. Authentication can take place over a virtual private network (VPN), enterprise Wi-Fi, or web portal. These use protocols to create a secure connection between the client machine, the remote access device, and the authentication server. This would allow the employee to access the company's internal resources from their home network.

Windows local sign-in is incorrect because local sign-in is used when the user is physically present at the computer and is logging in directly. It wouldn't help the employee access the company's internal resources from their home network.

Windows network sign-in is incorrect because network sign-in is used when the user is on the same network as the resources they are trying to access. In this case, the employee is not on the company's network, so this wouldn't resolve the issue.

Linux authentication is incorrect because the question specifically asks about Windows authentication. Linux Authentication would not be applicable in this scenario.

q_authent_methods_sso_sec8

Which of the following authentication methods specifically allows users allows users to access multiple systems, applications, or websites using only a single set of credentials?

Answers:

- ***Single sign-on (SSO)**
- Directory services
- Federation
- Attestation

Explanation:

Single sign-on (SSO) allows users to access multiple systems, applications, or websites using only a single set of credentials.

While directory services implements single sign-on for resources on the network, it is not used to refer to single sign-on.

Federation is the notion that a network needs to be accessible to more than just a well-defined group of employees. A company might need to open parts of its network to partners, suppliers, and customers.

Attestation is a protocol used to prove that software can be trusted, telling the remote user that the application or OS software is legitimate and certified.

q_authent_methods_tgt_sec8

You are a network administrator for a company that uses Kerberos for network authentication. An employee is having trouble accessing network resources and you suspect it's an authentication issue.

As part of your troubleshooting process, you decide to check the initial step in the Kerberos single sign-on process.

What should you be looking for?

Answers:

- The principal's request for a service ticket (ST)
- ***The principal's request for a ticket-granting ticket (TGT)**
- The principal's request for a key distribution center (KDC)
- The principal's request for a Secure Shell (SSH)

Explanation:

The principal's request for a ticket-granting ticket (TGT) is the correct answer. The first step in the Kerberos single sign-on process is for the principal (user or service) to request a TGT from the Authentication Service.

The principal's request for a service ticket (ST) is incorrect because the service ticket is not the initial step in the Kerberos process. The service ticket is requested after the TGT has been granted.

The principal's request for a key distribution center (KDC) is incorrect because the principal does not request a KDC. The KDC is a part of the Kerberos system that contains the authentication service and the ticket-granting service.

The principal's request for a Secure Shell (SSH) is incorrect because SSH is a protocol for secure remote login and other secure network services over an insecure network, not a part of the Kerberos authentication process.

q_sso_biometric_parameters_secp8

Which of the following is NOT a parameter considered for biometric authentication?

Answers:

- Universality
- Uniqueness
- Permanence
- Collectability
- ***Color**

Explanation:

The color of the biometric feature does not play a role in the authentication process as it does not contribute to the uniqueness or permanence of the biometric feature.

The following are biometric features:

- Universality refers to the fact that the physical attribute being measured should be present in every individual.
- Uniqueness means that the physical attribute should be distinctive enough to distinguish between individuals.
- Permanence refers to how well the specified attribute holds up to aging.
- Collectability refers to how easy it is to acquire the measurable attribute.

q_sso_crossover_secp8

Which of the following defines the crossover error rate for evaluating biometric systems?

Answers:

- The rate of people who are given access when they should be denied access.
- The rate of people who are denied access when they should be allowed access.
- The number of subjects or authentication attempts that can be validated.
- ***The point where the number of false positives matches the number of false negatives in a biometric system.**

Explanation:

The crossover error rate, or the equal error rate, is the point where the number of false positives matches the number of false negatives in a biometric system.

A false negative (or Type I error) occurs when a person who should be allowed access is denied access.

A false positive (or Type II error) occurs when a person who should be denied access is allowed access.

The processing rate, or system throughput, identifies the number of subjects or authentication attempts that can be validated.

q_sso_facial_recognition_secp8

You are a security manager at a large public event venue. You need to implement a biometric system that can quickly and non-intrusively collect data from a large crowd of people for identification purposes.

Which biometric collection method would be the most suitable for this scenario?

Answers:

- Fingerprint
- Retina
- Iris
- ***Facial**
- Voice

Explanation:

Facial recognition is the most suitable method for this scenario. It can quickly scan multiple faces in a crowd from a distance, making it non-intrusive and efficient for large-scale identification.

While fingerprint recognition is a reliable method, it is not suitable for a large crowd as it requires individual contact with a scanner and can slow down the process significantly.

Retina scanning is highly accurate but requires close contact and can be seen as intrusive. It is not suitable for quickly scanning a large crowd.

Iris recognition is also highly accurate but requires individuals to be close to the scanner and can be seen as intrusive. It is not suitable for quickly scanning a large crowd.

Voice recognition requires quiet environments and can be affected by background noise, making it unsuitable for a large public event venue.

q_sso_failure_to_enroll_secp8

You are the head of security at a large corporation and have recently implemented a new biometric authentication system for access to the company's facilities.

After a few weeks, you notice that a significant number of employees are having trouble registering their biometric data into the system.

Which metric would be most relevant to assess this issue?

Answers:

- False rejection rate (FRR)
- False acceptance rate (FAR)
- Crossover error rate (CER)
- ***Failure to enroll rate (FER)**
- Throughput (speed)

Explanation:

Failure to enroll rate (FER) measures incidents in which a template cannot be created and matched for a user during enrollment. This is the most relevant metric to assess the issue of employees having trouble registering their biometric data into the system.

The following are less relevant to the scenario:

- False rejection rate (FRR) measures the number of valid subjects who are denied access. It would be relevant if legitimate employees were being denied access after successful enrollment, not during the enrollment process.
- False acceptance rate (FAR) measures the number of unauthorized users who are mistakenly allowed access. It would be relevant if unauthorized individuals were gaining access to the facilities, not when employees are having trouble enrolling.
- Crossover error rate (CER) expresses the point at which FAR and FRR meet, with a low value indicating better performance. It would be relevant for assessing the overall performance of the biometric system, not specifically the enrollment issue.
- Throughput (speed) measures the time required to create a template for each user and the time required to authenticate. It would be relevant if the issue was about the speed of the authentication process, not the enrollment process.

q_sso_fingerprint_recognition_secp8

You are a security consultant tasked with implementing a biometric authentication system for a small business. The business owner wants a system that is cost-effective, non-intrusive, and relatively simple for employees to use.

Which biometric authentication method would you recommend?

Answers:

- Retina scanning
- Iris recognition
- Facial recognition
- ***Fingerprint recognition**
- Vein recognition

Explanation:

Fingerprint recognition is cost-effective, non-intrusive, and simple to use, making it the most suitable option for a small business. The technology required for scanning and recording fingerprints is relatively inexpensive and straightforward.

The following are not as ideal in this scenario:

Retina scanning is highly accurate but can be intrusive as it involves shining light into an individual's eye. It's also not as cost-effective as other options, making it less suitable for a small business.

Iris recognition is also highly accurate, it can be costly to implement and may be seen as intrusive by some individuals, making it less ideal for a small business.

Facial recognition can be affected by changes in lighting, the individual's expression, or even their hairstyle. It can also be more costly to implement than fingerprint recognition.

Vein recognition, while highly accurate and secure, requires more expensive technology and can be seen as intrusive, making it less suitable for a small business.

q_sso_gait_recognition_secp8

You are a security consultant for a high-security facility. The facility is looking for a unique, non-intrusive biometric system that can identify individuals even when they are not directly interacting with the system (e.g., not touching a scanner or speaking into a microphone).

Which biometric collection method would be the MOST suitable for this scenario?

Answers:

- Fingerprint
- Retina
- Iris
- Facial
- ***Gait**

Explanation:

Gait recognition analyzes the unique way individuals walk. It can identify individuals from a distance and does not require direct interaction with the system, making it the most suitable option for this scenario.

While fingerprint recognition is reliable, it requires individuals to directly interact with the system by placing their finger on a scanner. It would not meet the facility's requirement for non-direct interaction.

Retina scanning is highly accurate but requires close contact and can be seen as intrusive. It also requires direct interaction with the system, which does not meet the facility's requirements.

Iris recognition is also highly accurate but requires individuals to be close to the scanner. It requires direct interaction and can be seen as intrusive, which does not meet the facility's requirements.

Facial recognition can identify individuals from a distance, but it requires a clear view of the face, which may not always be possible in all scenarios within the facility.

4.3 Authorization

As you study this section, answer the following questions:

- How is authorization different from authentication?
- How does an access control list (ACL) help to increase network security?
- What is the difference between a Discretionary access control list (DACL) and a system access control list (SACL)?

In this section, you will learn to:

- Examine the access token

The key terms for this section include:

Term	Definition
Authorization	Granting a user on the computer system the right to use a resource.
Access control list (ACL)	A collection of access control entries that determines which users are allowed or denied access to an object and the privileges given to that user.
Effective permissions	Access rights are cumulative, giving the user combined permissions from multiple groups.
Deny permissions	Always override Allow permissions.

This section helps you prepare for the following certification exam objectives:

Exam	Objective

CompTIA Security+ SY0-701	1.2 Summarize fundamental security concepts.
	• Authentication, Authorization, and Accounting (AAA)
	  ○ Authorization models
	1.4 Explain the importance of using appropriate cryptographic solutions.
	• Obfuscation
	  ○ Tokenization
	2.5 Explain the purpose of mitigation techniques used to secure the enterprise.
	• Access control
	  ○ Access control list (ACL)
	  ○ Permissions
	4.6 Given a scenario, implement and maintain identity and access management.
	• Permission assignments and implications

Exam	Objective
	• Single sign-on (SSO) • Access controls ○ Discretionary
TestOut Security Pro	2.5.2 Access control • 2.5.2.1 Access control list (ACL) • 2.5.2.2 Permissions 4.6.8 Access control • 4.6.8.3 Role-based

4.3.1 Authorization (Lesson Video)

Transcript:

In this video, I'll go over authorization. Although you'll probably hear the terms authorization and authentication used interchangeably, they're actually quite different.

First, authentication asks the user who they are and verifies the user's identity so they can access a system. Authorization is what comes after this. It verifies the user's permissions to determine which specific resources the user is allowed access to. Authentication is validated using login credentials, and authorization is validated using an access control list, or ACL.
An ACL is a list of permissions attached to a resource, such as a file or folder. The ACL lists several entries known as access control entries, which are basically users or groups that have access to the resource. Groups allow for efficient administration and make security implementation easier.
A New Technology File System access control list, or NTFS ACL, contains a DACL and an SACL. These are two distinct ACLs types. The D in DACL stands for Discretionary, and the S in SACL stands for System. So Discretionary ACLs specify permissions, and System ACLs are used to keep track of who's accessing a resource and making changes to it.
Another Microsoft term is security principals. Security principals include user accounts, computer accounts, and security group accounts. Each security principal has a unique Security ID called an SID. The system keeps track of all SIDs so that when a user logs onto a Microsoft system, the system creates an access token for him or her.
The access token includes the user account's SID, the SIDs of all security groups the user belongs to, and a list of the user's rights or privileges. User rights are rights that specific users have on the system. These are also known as privileges, and they're defined by the Local Security Policy or through the Microsoft Group Policy. When a user tries to access a resource, such as a shared folder, the user's access token with its SID is compared against the SIDs of the shared folder. If there's a match, the user can gain access to the resource.
For example, let's say that Frank attempts to access the Sales folder. When he does, the system reads the folder's ACL, which contains all users' and groups' SIDs that allow file access. When we look at the ACL here, we see that SID 5 has Read access, SID 7 has Read & write access, and SID 12 has Full control. This means that it's probably an administrator account. When we look at Frank's access token, we see that he has a user SID of 3, and that he's also been assigned to Group1, which has an SID of 7. So when the system compares his token with this folder's ACL, there's one match. Frank has access to the Sales folder because he's a member of Group1. No other SIDs match up, so Frank is only granted Read & write file access. This is a simple example, but you get the idea.
NTFS permissions get a lot more complicated than this. But in essence, they're just a way to allow users access to certain Microsoft system resources.

That's it for this lesson. In this lesson, we discussed authorization. While we mainly focused on Microsoft NTFS systems, most of the terms we used are generic. Access control lists are widely used for assigning user permissions and privileges.

4.3.2 Cumulative Access (Lesson Video)

Transcript:

In this video, I'm going to talk about cumulative access. As a security administrator, one of your most important jobs is to control both file system and network resource access. You do this using permissions, privileges, and roles.

Permissions, privileges, and roles are usually cumulative. As such, it's easy to inadvertently give someone access to something that you don't want them to have access to. When you assign rights to users, groups, and other accounts, you need to ask yourself, "Do I really want this person to have this access level?" If your system supports the concept of a role, you can create a role definition. In some systems, it might called be a role object. This role or role object isn't actually a user account, but we use it in a similar way. A role is kind of like a template. You build a role, add the desired access, and then you can use that shell of an account to create new accounts as needed.
For example, let's say that Sally is the payroll assistant. She's worked at the company for ten years and has access to all the files and systems that she needs to be effective at her job. One day, Sally is promoted to payroll manager, and Frank is hired to take over as payroll assistant. If her user account was created from scratch, you'd have to start all over to redesign Frank's account. But if you'd created Sally's account using a role specifically made for payroll employees, you could use that same role to create Frank's new account. This makes things much easier and much more secure. We simply add or remove users from roles instead of having to remember which user needs which privileges added or removed.
Not every system uses the roles concept. For example, Windows Active Directory doesn't have an object called a role object. But Active Directory groups are more or less the same thing.
Whatever system you're using, you need to remember that each user receives all member groups' access privileges in addition to its own specific assignments. Cumulative access can get out of control pretty quickly. Over time, users end up with too much access to the file system. The best way to reduce this problem is to limit a single user's assigned number of roles. If you can help it at all, don't assign multiple roles.
Take Sally and Frank, for example. Currently, they're both in payroll. But now that Sally is a manager, she needs access to additional employee information, like salaries and financial history. You could solve this by leaving Sally in her current payroll employee role and adding her to the HR role. By doing this, though, you're probably giving her access to too much information. She obviously needs access to salary information, but she doesn't need access to employee reviews or disciplinary files. Instead, you should probably create a payroll management role. If you're dealing with a situation where none of the roles provide the access level needed for a given user, it's a much better option to create a completely new role that has the necessary access level instead of assigning that user to multiple roles.
That's it for this lesson. In this lesson, we talked about cumulative access in relation to roles and groups. We also discussed the importance of limiting a single user's number of roles.

4.3.3 Authorization Facts

Authorization is the process of determining what rights and privileges a particular entity should have on available resources and then enforcing those rights.

This lesson covers the following topics:

- Authorization
- Permissions, privileges, and roles
- Access control lists (ACLs)
- Authorization with single sign-on

Authorization

Authorization means granting the account configured for the user, or the role for a group of users, the rights to use a resource. Authorization manages the privileges granted on resources such as computers, files, and printers. When managing access to resources, be aware of the following:

- A group account is a collection of user accounts that is useful when establishing file permissions and user rights because when many individuals need the same level of access, a group could be established containing all the relevant users.
- When you assign permissions to a group, these permissions are granted to all group members.
- On a Microsoft system, a user right is a privilege or action that can be taken on a system, such as logging on, shutting down, backing up the system, or modifying the system's date and time.
- Permissions apply to objects (files, folders, printers, etc.), while user rights apply to the entire system (the computer).

An authorization model determines how these rights are granted. For example, in a discretionary model, the object owner can allocate rights. In a mandatory model, rights are predetermined by system-enforced rules and cannot be changed by any user within the system.

Permissions, Privileges, and Roles

A crucial part of any security administrator's job is to control access to resources. For example, with file system security, each object in the file system has an access control list (ACL) associated with it. The ACL contains a list of accounts (principals) allowed to access the resource and the permissions they have over it. The order of ACEs in the ACL is essential in determining effective permissions for a given account. ACLs can be enforced by a file system that supports permissions, such as NTFS, ext3/ext4, or ZFS.

Types of permissions are described in the table below.

Permission Type	Description
Effective permissions	Access rights (permissions) are cumulative. If you are a member of two groups with different permissions, you have the combined permissions of both groups (this is known as effective permissions). Effective permissions are the combination of inherited permissions and explicit permissions.
Deny permissions	Deny permissions always override Allow permissions. For example, if a user belongs to two groups and specific permission is allowed for one group and denied for the other, the permission is denied. However, the exception to this rule comes with inherited permissions. If an object has an explicit Allow permission entry, inherited Deny permissions do not prevent access to the object. Explicit permissions override inherited permissions, including Deny permissions.
Cumulative permissions	The following suggestions will help you plan permissions and mitigate issues related to cumulative permissions: • Identify the users and their access needs (the actions each user needs to be able to perform). • Create a group for each type of user with similar needs. Then, make the users members of the appropriate group. • Assign each group (not the user) the permissions appropriate to the group's data access needs. Grant only the necessary permissions. • Take inheritance into account as you assign permissions. Inheritance means permissions granted to a parent container object flow down to child objects

Permission Type	Description
	within the container. Set permissions as high as possible on the parent container and allow each child container to inherit the permissions. • Override inheritance on a case-by-case basis when necessary.

Access Control Lists (ACLs)

Access control lists (ACLs) in computer systems and networks are used to enforce access control policies. An ACL is a list of rules or entries that specify which users or groups are allowed or denied access to specific resources or perform certain actions. In networks, ACLs are associated with routers, firewalls, or similar devices and define rules that determine how network traffic is filtered or forwarded based on criteria like source IP addresses, destination IP addresses, ports, or protocols.

ACLs can help to control network access and protect against unauthorized or malicious activities. ACLs control access to files, directories, or system resources in operating systems and file systems. Each access control entry (ACE) typically contains a user or group identifier and associated permissions controlling actions that are allowed or denied. These permissions often include read, write, execute, and sometimes more granular limits such as modify, delete, or list.

While ACLs offer flexibility and control, managing complex access control policies with numerous ACL entries can become challenging. Complexity increases the risk of misconfigurations. Therefore, proper planning, periodic reviews, and best practice configurations are essential when implementing and maintaining ACLs.

For example, Discretionary access control (DAC) is based on the primacy of the resource owner. In a DAC model, every resource has an owner. The owner creates a file or service, although ownership can be assigned to another user. The owner has full control over the resource, and they can modify its access control list (ACL) to grant rights to others.

An access control system ensures that an information system meets the goals of the CIA triad. Access control governs how subjects/principals may interact with objects. Subjects are people, devices, software processes, or any other system that can request and be granted access to a resource. Objects are the resources. An object could be a network, server, database, app, or file. Subjects are assigned rights or permissions on resources.

A security principal is an object that can be given permissions to an object. Security principals include user accounts, computer accounts, and security group accounts.

- Each security principal is given a unique identification number called a Security ID (SID).
- When a security principal logs on, an access token is generated. The access token controls access to resources and contains the SID for the user or computer, for all groups the user or computer is a member of, and the user rights granted to the security principal.
- When the security principal tries to access a resource or take action, information in the access token is checked. For example, when a user tries to access a file, the access token is checked for the user's SID and all groups. The SIDs are then compared to those in the object's DACL to identify permissions that apply.
- On a Microsoft system, the access token is only generated during authentication. Changes to group memberships or user rights do not occur until the user logs on again and a new access token is created.

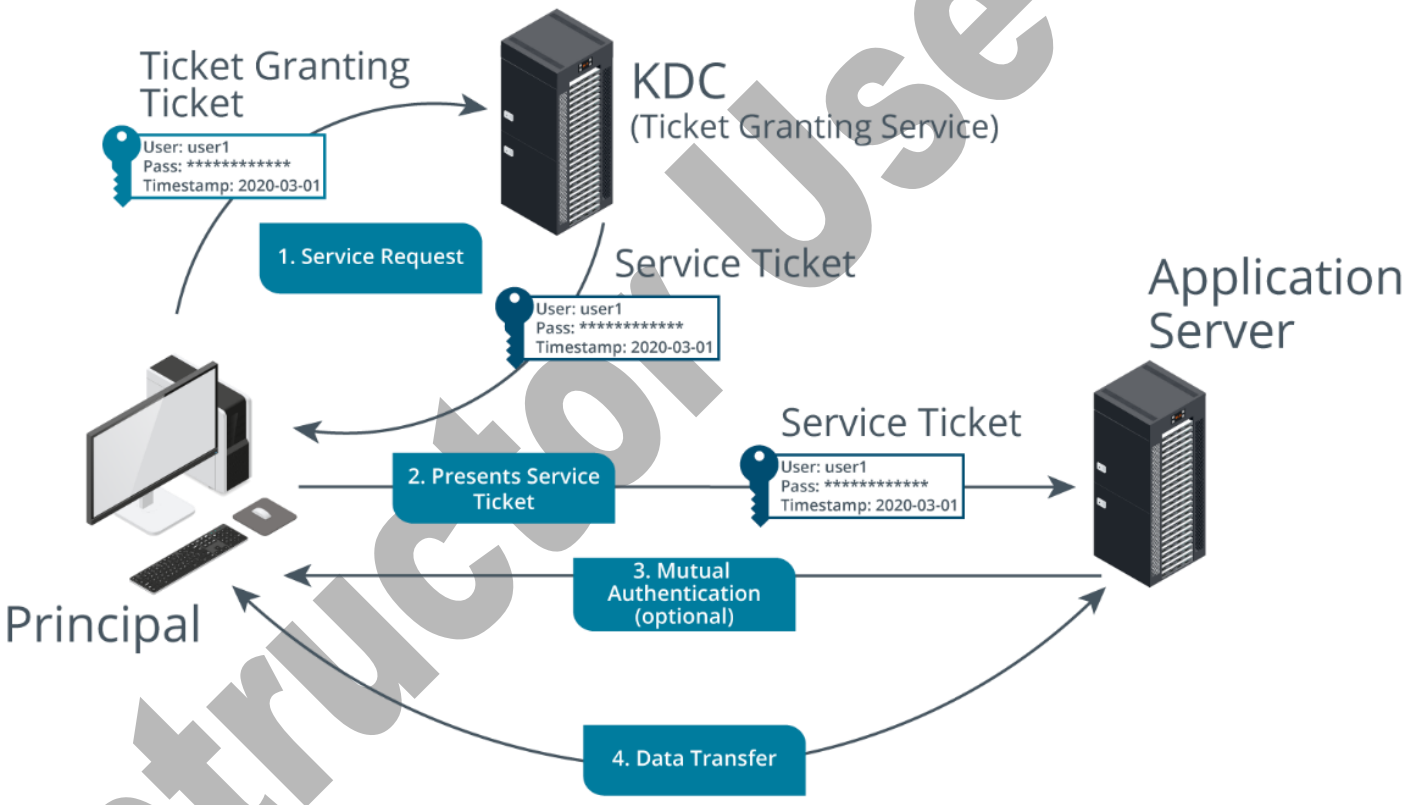
Authorization with Single Sign-on

After completing authentication, the client can decrypt the Ticket Granting Service (TGS) session key but not the Ticket Granting Ticket (TGT) . This establishes that the client and key distribution center (KDC) know the same shared secret and that the client cannot interfere with the TGT.

- To access resources within the domain, the principal requests a service ticket (a token that grants access to a target application server). This process of granting service tickets is handled by the TGS.
- The principal sends the TGS a copy of its TGT and the name of the application server it wishes to access, plus an authenticator consisting of a time-stamped client ID encrypted using the TGS session key.

The TGS should be able to decrypt both messages using the KDC's secret key for the first and the TGS session key for the second. This confirms that the request is genuine. It also checks that the ticket has not expired and has not been used before (replay attack). The TGS service responds with the following:

- **A Service session key** — is used between the client and the application server. This is encrypted with the TGS session key.
- **A Service ticket** — contains information about the principal, such as a time stamp, system IP address, Security Identifier (SID) and the SIDs of groups to which it belongs, and the service session key. This is encrypted using the application server's secret key.
- The principal forwards the service ticket, which it cannot decrypt, to the application server and adds another time-stamped authenticator, which is encrypted using the service session key.



Kerberos Ticket Granting Service. (Images © 123RF.com.)

- The application server decrypts the service ticket to obtain the service session key using its secret key, confirming that the principal has sent it an untampered message. It then decrypts the authenticator using the service session key.
- Optionally, the application server responds to the principal with the time stamp used in the authenticator, which is encrypted using the service session key. The principal decrypts the time stamp, verifies that it matches the value already sent, and concludes that the application server is trustworthy.

This means that the server is authenticated to the principal (referred to as *mutual authentication*). This prevents an on-path attack, where a malicious user could intercept communications between the principal and server.

- The server now responds to access requests (assuming they conform to the server's access control list).

One of the noted drawbacks of Kerberos is that the KDC represents a single point of failure for the network. In practice, backup KDC servers can be implemented (for example, Active Directory supports multiple domain controllers, each of which is running the KDC service).

4.3.4 Examining the Access Token (Demo Video)

Transcript:

In this demonstration, we're going to spend some time working with access tokens. We're going to look at the access token that's granted to a Windows user when they log in to a Windows domain.

I'm currently logged in to this Windows 10 system as the dfellows user in the CorpNet.xyz domain. We can verify this using the â€˜whoami' command at the command prompt. Press Enter, and we see that I'm logged in as dfellows in the CorpNet domain, which is nice to know, but it's not terribly useful. But if we do a â€˜whoami' with the â€˜/all' option, then we see more interesting information. We see the access token that was granted to the dfellows user when I initially logged in.
One of the first things we see is the SID, which is a unique number associated with my user account. In addition, you see my domain and username. We also see the SID of all the different groups that my user account is a member of. First, we see all of the default local groups it's part of. Down here, we also see the domain groups that my account is a member of, such as the Night Shift group, the Day Shift group, and the Enterprise Admins group.
The third section of the access token is Privileges Information. These privileges are also known as user rights. It tells me what my user account can do on the system. For example, there's the Change the system time user right, which my account doesn't have. For me, it's disabled along with a lot of other rights.
Let's go back up here and look at the SID. The key thing to remember about this number, the security identifier, is the fact that when I try to access a file or folder in the NTFS file system, the SID in my access token is compared to the SIDs in the Access Control List of the file or folder. If they match up, I get some form of access, or I may be denied access depending on how the ACL is configured.
At this point, let's go ahead and switch over to my domain controller. On my SRV2019 domain controller, which is the domain controller for my CorpNet.xzy domain, I want to verify the group membership of my dfellows user account that we just looked at.
To do this, I'll come over to Tools and go to Active Directory Users and Computers. In the CorpNet domain, I need to locate my dfellows user account. I happen to know that dfellows is in the CorpNetUsers organizational unit. I'll Select it. Right-click on the account. Let's go to Properties and go to the Member Of tab, and I can see a list of all of the groups that my user is a member of.
I'm a member of Day Shift, Domain Admins, Domain Users, Enterprise Admins, and Night Shift. However, there are many other groups in my domain that I could be a member of. For example, in marketing, I have a group called Marketing. But I'm not currently a member of that group.
To see how the access token determines the level of access I have to files and folders in the NTFS file system, let's come down to File Explorer and go to my C: drive. We have a folder here named SharedFiles, and this folder is currently shared. Let's see who it's shared with. Click on Properties. Go to Sharing. Let's go to Advanced Sharing and then to Permissions.
Here, you can see that two groups have been granted access to this folder. These are the groups that are in the ACL of the SharedFiles folder. Anyone who's a member of either of these groups receives the permissions defined below.
We want to see how the access token works, so let's remove these groups--remember, my dfellows user account is a member of both of these. Let's go ahead and remove these groups and add another group that my user account isn't a member of, for example, the Marketing group we just looked at.
Let's grant Marketing full control. Let's remove Everyone, click Remove, and then click Administrators. Click Remove once again. Hit Apply, OK, OK again, and Close. The SharedFiles folder is now shared with any user who's a member of Marketing. dfellows is not a member of Marketing. Let's go ahead and see what happens now if I try to access this folder from my client system.

Back on my client system, where I'm still logged in as the dfellows user, I come down to Search, and let's enter â€˜\\srv2019'. Press Enter, and it should open File Explorer with a list of all the shares currently available on the file server. There's our SharedFiles share.
Within this share, there are a couple of documents. Let's see if I can access them. If I double-click, there's a problem. I can't access the folder because of the Access Control list. My access token isn't there. I'm not on the list, so I can't access the share. This is an example of Implicit Deny. Remember, with Implicit Deny, if there's no match, then, automatically, access is denied. That's the case here. Only a user who's a member of the Marketing group can access this share.
Let's go ahead and fix this. I'll close this window.
Let's go back over to the domain controller and add the dfellows user to the Marketing group. Here's my Marketing group that I want to add my user account to. I can do this in two ways. I can right-click here, go to Properties, and then go to the Members tab and add my user account there. Or I could come to the user account itself, right-click, and say Add to Group. Either way, it does the same thing.
Let's add it to the Marketing group. Group operation was successful. Click OK. Let's just verify that. Go to Properties. Go to the Member Of tab. Sure enough, I'm a member of Marketing now. OK.
Now let's go back over to my Windows 10 workstation and try accessing the share again. Let's come back down to Search, and let's access our list of shares available. There's the SharedFiles share. If I double-click on it, I still can't access it. Why not? I was added to the Marketing group. The Marketing group is in the Access Control list of the share. In fact, it has full control over the share. Why can't I access it?
The key thing to remember here is that the access token over here, for my dfellows user account, was created when I logged in. I made the change to my group membership for my user account after I had already logged in. In fact, if we come down to the bottom and we type the â€˜whoami /all' command again, you can see that I'm still a member of just Research, Support, and Enterprise Admins as far as my access token is concerned. It doesn't list the Marketing group. That's because we've made the change in group membership since I logged in.
In order to fix this and add the Marketing group to the access token, I have to log off as dfellows on the system and then log back in as that user account again, which will re-issue my access token. This should make this account a member of the Marketing group and give us access to the shared folder.
Let's go ahead and do that. All right. I've logged off, and now I've logged back in. Let's check my access token to see if the Marketing group has been added. Do â€˜whoami /all' one more time. Notice, when I scroll down here and look, I can see that the Marketing group has been added.
Let's test it. We'll come down here, open up my run box again, and browse the various shares available on the server. There's my ShardFiles share. If I double-click on it this time, I have access to the files. Remember, we gave the Marketing group full control, so I'm actually allowed to go in and have access to the file. I can add, modify, delete, or do anything that someone with full access can do. I'm able to do that because now, the Marketing group is in the access token of the dfellows user account.
That's it for this demonstration. In this demo, we looked at the access token that's assigned to a Windows user when they log in to the Windows domain. We've looked at the group membership contained within the access token. Then we did a little experiment to show how the access token is assigned when the user logs in, and any changes made to the user account's group membership aren't reflected until the next login.

4.3.5 Implement an Access Control Model

4.3.6 Practice Questions (Section Quiz)

q_authorize_acl_secp8

Which security mechanism uses a unique list that meets the following specifications:

- The list is embedded directly in the object itself.
- The list defines which subjects have access to certain objects.
- The list specifies the level or type of access allowed to certain objects.

Answers:

- Mandatory access control
- Conditional access
- Hashing
- ***User ACL**

Explanation:

A user ACL (user access control list) is a security mechanism that defines which subjects have access to certain objects and the level or type of access allowed. This security mechanism is unique for each object and embedded directly in the object itself.

Mandatory access control (MAC) is an access control system based on classifications of subjects and objects to define and control access.

Conditional access is a way to enforce access control while also encouraging users to be productive wherever they are.

Hashing is a cryptographic tool that creates an identification code that is employed to detect changes in data.

q_authorize_authorize_secp8

What is the process of controlling access to resources such as computers, files, or printers called?

Answers:

- Mandatory access control
- Conditional access
- ***Authorization**
- Authentication

Explanation:

Authorization is the process of controlling access to resources such as computers, files, or printers.

Mandatory access control (MAC) is an access control system based on classifications of subjects and objects to define and control access.

Conditional access is a way to enforce access control while also encouraging users to be productive wherever they are.

Authentication is the verification of the issued identification credentials.

q_authorize_group_secp8

Which of the following objects identifies a set of users with similar access needs?

Answers:

- ***Group**
- DACL
- SACL
- Permissions

Explanation:

A group is an object that identifies a set of users with similar access needs. Microsoft systems have two kinds of groups, distribution groups and security groups. Only security groups can be used for controlling access to objects.

A discretionary access control list (DACL) is an implementation of discretionary access control (DAC).

A system access control list (SACL) is used by Microsoft for auditing in order to identify past actions performed by users on an object.

Permissions define the rights and access users and groups have with objects.

q_authorize_permission_secp8

Which of the following identifies the type of access that is allowed or denied for an object?

Answers:

- DACL
- User rights
- SACL
- ***Permissions**

Explanation:

Permissions define the rights and access users and groups have with objects. Permissions are applied to objects such as files and folders.

A discretionary access control list (DACL) is an implementation of discretionary access control (DAC).

On a Microsoft system, a user right is a privilege or action that can be taken on a system, such as logging on, shutting down, backing up the system, or modifying the system date and time.

A system access control list (SACL) is used by Microsoft for auditing in order to identify past actions performed by users on an object.

q_authorize_sacl_secp8

Which of the following is used by Microsoft for auditing in order to identify past actions performed by users on an object?

Answers:

- DACL
- User rights
- ***SACL**
- Permissions

Explanation:

A system access control list (SACL) is used by Microsoft for auditing in order to identify past actions performed by users on an object.

A discretionary access control list (DACL) is an implementation of discretionary access control (DAC).

On a Microsoft system, a user right is a privilege or action that can be taken on a system, such as logging on, shutting down, backing up the system, or modifying the system date and time.

Permissions define the rights and access users and groups have with objects. Permissions are applied to objects such as files and folders.

q_authorize_security_secp8

Which type of group can be used for controlling access to objects?

Answers:

- ***Security**
- DACL
- Distribution
- Authorization

Explanation:

Only security groups can be used for controlling access to objects.

A discretionary access control list (DACL) is an implementation of discretionary access control (DAC).

Distribution groups cannot be used for controlling access to objects.

Authorization is the process of controlling access to resources such as computers, files, or printers.

q_authorize_service_ticket_secp8

You are a security administrator for a large organization that uses Kerberos for authentication.

One day, you receive a call from a user who is having trouble accessing a specific service on the network. You suspect that the issue might be related to the Kerberos service ticket.

Which of the following steps should you take first to troubleshoot this issue?

Answers:

- Invalidate all active service tickets for the user.
- ***Check the expiration time of the user's service ticket.**
- Request a new Ticket Granting Ticket (TGT) for the user.
- Change the user's password in the Kerberos database.

Explanation:

The first step in troubleshooting should be to check the expiration time of the user's service ticket. Kerberos service tickets have a limited lifespan for security reasons. If the service ticket has expired, the user will need to request a new one.

Invalidating all active service tickets for the user is a drastic step that could disrupt the user's access to other services. This should not be the first step in troubleshooting.

Requesting a new Ticket Granting Ticket (TGT) for the user is not necessary if the problem is specifically with the service ticket. The TGT is used to obtain service tickets, but it is not directly involved in accessing services.

Changing the user's password in the Kerberos database is a drastic step that could disrupt the user's access to the network. This should not be the first step in troubleshooting, and it is not directly related to the service ticket.

q_authorize_tgt_secp8

You are the IT security manager at a large organization that is implementing a single sign-on (SSO) solution for the first time. The SSO solution uses the Kerberos protocol.

During a meeting, your team discusses the following options for the initial step in the Kerberos authentication process.

Which option should be the initial step in the Kerberos authentication process?

Answers:

- The client sends a request to the Ticket Granting Service (TGS) for a service ticket.
- ***The client sends a request to the Authentication Server (AS) for a Ticket Granting Ticket (TGT).**
- The client sends a request to the service server for a service ticket.
- The client sends a request to the Key Distribution Center (KDC) for a session key.

Explanation:

The first step in the Kerberos authentication process is for the client to send a request to the Authentication Server (AS) for a Ticket Granting Ticket (TGT). The AS verifies the client's credentials and, if valid, issues a TGT. The TGT is then used to request service tickets from the TGS. This is the correct answer.

The client does not initially send a request to the Ticket Granting Service (TGS) for a service ticket. The TGS is involved later in the process, after the client has received a TGT from the AS.

The client does not initially send a request to the service server for a service ticket. The service server is involved later in the process, after the client has received a service ticket from the TGS.

While the Key Distribution Center (KDC) is a critical component of the Kerberos protocol, the client does not directly request a session key from the KDC. The KDC houses both the AS and the TGS, and it is the AS that initially provides the TGT.

Marcus White has just been promoted to a manager. To give him access to the files that he needs, you make his user account a member of the Managers group, which has access to a special shared folder.

Later that afternoon, Marcus tells you that he is still unable to access the files reserved for the Managers group.

What should you do?

Answers:

- ***Have Marcus log off and log back in.**
- Manually refresh Group Policy settings on his computer.
- Add his user account to the ACL for the shared folder.
- Manually refresh Group Policy settings on the file server.

Explanation:

On a Microsoft system, an access token is only generated during authentication. Changes made to group memberships or user rights do not take effect until the user logs in again and a new access token is created.

Use NTFS and share permissions, not Group Policy, to control access to files. In addition, Group Policy is periodically refreshed, and new settings are applied on a regular basis.

q_authorize_token_02_secp8

Which of the following terms describes the component that is generated following authentication and is used to gain access to resources following login?

Answers:

- ***Access token**
- Account policy
- Cookie
- Proxy

Explanation:

When a security principal logs on, an access token is generated. The access token is used to control access to resources and contains the following information:

- The security identifier (SID) for the user or computer
- The SID for all groups the user or computer is a member of
- User rights granted to the security principal

When the security principal tries to access a resource or take an action, information in the access token is checked. For example, when a user tries to access a file, the access token is checked for the SID of the user and all groups. The SIDs are then compared to the SIDs in the object's DACL to identify permissions that apply.

Account policies in Group Policy control requirements for passwords, such as minimum length and expiration times.

Cookies are text files that are stored on a computer to save information about your preferences, browser settings, and web page preferences. Cookies identify you (or your browser) to websites.

A proxy is a server that stands between a client and destination servers.

q_authorize_token_03_secp8

Lori, who has been a member of the Project Management group, was recently promoted to manager of the team. She has been added as a member of the Managers group.

Several days after being promoted, Lori needs to have performance reviews with the team she manages. However, she cannot access the performance management system. As a member of the Managers group, she should have the Allow permission to access this system.

What is MOST likely preventing her from accessing this system?

Answers:

- ***She is still a member of the Project Management group, which has been denied permission to this system. Deny permissions always override Allow permissions.**
- She is still a member of the Project Management group, which has been denied permission to this system. However, being a member of the Managers group should allow her to access this system. Allow permissions always override Deny permissions. There must be an explicit permission entry that is preventing her from accessing the management system.
- Her user object has been assigned an explicit Deny permission to the performance management system.
- Her user object has been assigned an explicit Allow permission to the performance management system, but she inherited the Deny permission assigned to the Project Management group (which she still belongs to). Inherited Deny permissions override explicit Allow permissions.

Explanation:

The most likely cause of this problem is that Lori is still a member of the Project Management group, which has been denied permission to this system. Deny permissions always override Allow permissions.

Allow permissions do not override Deny permissions unless the Allow permission is explicitly assigned and the Deny permission is inherited. It is unlikely that her user object has been assigned an explicit Deny permission to the performance management system since best practice is to assign permissions to groups, not to users.

q_authorize_user_secp8

Which of the following is a privilege or action that can be taken on a system?

Answers:

- DACL
- ***User rights**
- SACL
- Permissions

Explanation:

On a Microsoft system, a user right is a privilege or action that can be taken on a system: such as logging on, shutting down, backing up, or modifying the date and time. User rights apply to the entire system.

A discretionary access control list (DACL) is an implementation of discretionary access control (DAC).

Microsoft uses a system access control list (SACL) for auditing in order to identify past actions performed by users on an object.

Permissions define the rights and access users and groups have with objects. Permissions are applied to objects such as files and folders.

4.4 Active Directory Overview

As you study this section, answer the following questions:

- What is the purpose of a domain?
- How do organizational units (OUs) simplify security administration?
- How do computer policies differ from user policies?
- What is the order in which Group Policy objects (GPOs) are applied?

In this section, you will learn to:

- Join a domain
- Manage Active Directory objects
- Create OUs
- Delete OUs
- Use Group Policy
- Create and link a GPO
- Create user accounts
- Manage user accounts
- Create a group
- Create Global Groups

The key terms for this section include:

Term	Definition
Domain	A domain is an administratively defined collection of network resources that share a common directory database and security policies. The domain is the basic administrative unit of an Active Directory structure.
Tree	A tree is a group of related domains that share the same contiguous DNS namespace.
Forest	A forest is a collection of related domain trees. The forest establishes the relationship between trees that have different DNS namespaces.
Organizational unit (OU)	An organizational unit is similar to a folder. It subdivides and organizes network resources within a domain.
Object	Each resource within Active Directory is identified as an object.
Domain controller	A domain controller is a server that holds a copy of the Active Directory database. It is also the copy of the Active Directory database on a domain controller that can be written to.
Replication	Replication is the process of copying changes to Active Directory on the domain controllers.
Member servers	Member servers are servers in the domain that do not have the Active Directory database.
Policy	A policy is a set of configuration settings applied to users or computers.

This section helps you prepare for the following certification exam objectives:

Exam	Objective
CompTIA Security+ SY0-701	1.2 Summarize fundamental security concepts. • Authentication, Authorization, and Accounting (AAA)

Exam	Objective
	4.5 Given a scenario, modify enterprise capabilities to enhance security. • Operating system security ○ Group Policy
TestOut Security Pro	1.1 Manage identity 1.1.1 Manage Windows local and domain users and groups 1.1.3 Manage Active Directory OUs

4.4.1 Active Directory Introduction (Lesson Video)

Transcript:

In this lesson, we're going to introduce you to the basics of Microsoft's Active Directory service, or AD service. Using Active Directory can be beneficial when managing larger computer environments.

In standalone and workgroup networking models, all computer management takes place on each individual computer. This includes authentication and security.
This means that every computer stores its own authentication independently from any other computer.
Although these models may work well in small environments of 10 to 15 computers, they don't work well in larger environments. This is because duplicate sets of user accounts must be created and maintained on each computer.
To overcome these types of challenges, Microsoft created Active Directory services.
AD is a centralized database that provides three major benefits: centralized resources and security administration, single logon for access to global resources, and simplified resource location.
Let's first discuss centralized resources and security administration.
This means that an administrator can manage and secure their network resources and security objects from a single point. That single point is the Active Directory database.
This means thatâ€”unlike the workgroup networking modelâ€”they don't have to go from computer to computer to implement these features.
This feature is probably the most compelling reason for using Active Directory.
The second benefit is that you can provide access to the network resources on any server in the domain with a single logon.
So once a user has been created on a domain controller, that user can be granted access to any resource in the networkâ€”from any network computer.
For example, if this computer is this user's main desktop computer, he or she could authenticate or log in to this computer daily. He or she would never have to worry about restricted access.
However, if the user needed this computer to attend a meeting in a conference room, they could also login or authenticate from it. They would still have access to the same resources they had when logged in from the main computer.
The third benefit is the ability to simplify access to files and print resources.
This is done by allowing files and print resources to be published on the network. Once done, a user can search the Active Directory database for the desired resource and then securely access it.
For example, if our user authenticated the domain from this computer but wanted to access a shared folder located on this computer, they wouldn't need to directly reauthenticate to that computer.
Instead, they could simply access the folder for which they had been granted rights.
Likewise, if our user needed to print files, they could find and print to the network printer without needing to reauthenticate to the printer.
As you can imagine, it's going to take a little more work to implement these features than would be required to manage a workgroup network.

As such, you need to be familiar with the various components that comprise an Active Directory implementation.
Let's look at what they are.
The first thing we need to look at is the concept of a domain.
A domain is an administratively defined collection of network objects or resources that share a common directory database and security policies.
The domain is the basic administrative unit of Active Directory. It's the Active Directory database.
As such, it stores our user information and our security information.
For example, in this network, you can see we're working with the CorpNet.xyz domain.
Notice that the domain is identified using a distinguished Domain Name System name, or DNS name, of CorpNet.xyz.
But sometimes we refer to a domain by just its domain or common name. In this case it's CorpNet.
Another component of Active Directory is the domain controller.
A domain controller, also called a DC, is a Windows server that holds a copy of the Active Directory database.
A single domain can have multiple domain controllers, with each domain controller containing a copy of the AD database.
In addition, any changes that need to be made to the Active Directory database can be made to any of the domain controllers. Then that change will be sent out to all the other domain controllers within the domain.
This process is called replication.
For example, if I create a new user account on this domain controllerâ€" through the process of replicationâ€"that same user account would be copied or replicated to the Active Directory databases on all the other domain controllers in the domain.
This allows Active Directory to maintain consistency between all the domain controllers. No matter which one you're working with, it's going to have the exact same information as all the other ones in that domain.
Next, we need to look at organizational units, or OUs.
An OU is like a folder that's used to subdivide and organize resources within the domain.
Examples of organizational units are shown here. We have Marketing, Sales, and Research.
An organizational unit is also known as a container object.
This means that it can contain other domain objects and can even contain other organizational units. Take advantage of this if you want to nest multiple OUs within a given organization unit.
For example, when I expand the Sales OU, you see that I've used several OUs to organize my sales team by region.
OUs can also contain other types of objects, such as user objects, computer objects, and so on.
Besides logically organizing your network resources, OUs also help you simplify your security administration.
For example, if all my users in the Research Department need a similar level of access to network resources, then I can apply the necessary security policies only to the Research OU. Every user will receive those same policies.
This eliminates the need to go through each Research OU user and make the same security changes over and over.
It also means that if I add a new user to this OU, that user will automatically receive the same security privileges. They don't need me to manually assign them anything.
Likewise, if I were to delete a user from the Research OU, that user would lose whatever security privileges they received in the first place.
Active Directory also includes a special type of container object called a built-in container.
A built-in container looks like an organizational unit, but it's not.
Some of the built-in containers shown here include Foreign Security Principles, Managed Service Accounts, and Users.
Notice that the icons we use for built-in containers are slightly different than those used for the OUs we looked at just a minute ago.
Like the other type of organizational units, built-in containers can contain other objects and can be used to organize our Active Directory objects.
But, these built-in containers are created by default when the domain is initially installed. They're different from organizational units in several key ways.
For example, you can't create, move, rename, or even delete a built-in container.
In addition, they have very few properties that can be edited. There's also not much I can configure with one of these.
With organizational units, on the other hand, there's much more that can be configured.
In addition to organizational units and built-in containers, Active Directory also includes objects.
With Active Directory, each network resource is identified as an object.
For example, in the Research OU, you see I have four objects. Three user objectsâ€"Pascal, Paul, and Sailorâ€"and a group object named USA.
And there are many other object types used within Active Directory as well.
You can have objects for computers, for printers, and more.
Each of these objects contains attributes. Each attribute represents some bit of information about that object.

Let's suppose that we're viewing the attributes of the Sailor Olsen user object.
Some of the attributes associated with a user object are the user's name, phone number, email address, and so on.
These attributes are used for both locating and securing network resources.
Essentially, if you want someone to be able to log in to the domain and access the network resources, then you must create a user object for them within the domain.
That's it for this lesson.
In this video, we introduced you to Active Directory.
We first talked about Active Directory domains.
We talked about domain controllers.
We talked about organizational units.
We talked about built-in containers.
Then we talked about individual objects in Active Directory.

4.4.2 Joining a Domain (Demo Video)

Transcript:

In this demonstration, we're going to review how to join a Windows workstation to an Active Directory domain.

I'll come down to the Start button, right-click, and then go to System. Beside Related links, click on Domain or workgroup. This will launch our System Properties window. Toward the bottom of the window, you can see that it says, "To rename the computer or change to a domain or workgroup, click Change." That seems straightforward, so let's click on Change.
Down here, you can see it's part of a workgroup, and the name of the workgroup is WorkGroup. This is the default workgroup that's set up when you install a Windows system. It's not joined to a domain yet. We need to change that.
In order to join this system to a domain, we need to create a domain. That means we have to install a Windows server system, install Active Directory on it, make it a domain controller, and then configure a domain. Let's switch over to my Windows Server system.
As you can see here, on this server system, I've already done all of those tasks. This is my Windows server system. Note, over here, that it already has the Active Directory Domain Services role installed. DNS is installed, and the server is functioning as the domain controller for the domain named CorpNet.xyz.
Before we switch back over to the workstation system, I want to point out something very important: this server is also functioning as my DNS server for the domain. Depending on the implementation you're working in, this may or may not be the case in the real world. I've set it up this way for convenience in a demonstration environment. I have all of my services, including directory services and DNS, all running on the same system.
In a large implementation, it's very likely that the DNS server would be configured to run on a different server. We don't have to worry about that here. We just need to remember that this server, with an IP address of 10.10.10.5, is my DNS server for my CorpNet domain.
With that information in mind, let's go ahead and join this workstation to the CorpNet.xyz domain.
We need to get back to the System Properties window, where we were a few minutes ago. Keep in mind that there are a few different ways to get to System Properties, and as Windows evolves, it could be different in the future.
On the Computer Name tab, we have an option called Change. Click it. Notice we could change the computer name, here, if we wanted to. This is also where we can make this workstation a member of a domain.
I'm not going to do that just yet because currently, this workstation doesn't know how to contact the domain controller. It's not configured to use my Active Directory DNS server. We need to fix that before we can proceed.
Let's go down to our Network icon, down here in the notification area. Right-click and go to Network and Internet settings. We'll click here, where it says Ethernet. If I scroll down a bit, you can see our IP assignment, which is set to Automatic, or DHCP. Our IP is coming via DHCP, and so is our DNS information. And in this case, that's a problem Let's fix it.
If your network is set up so that your DHCP server is handing out the correct IP address for your Active Directory DNS server, you don't actually have to make any changes. If it's not, then you need to go manually specify the IP address pointing to the DNS server that's functioning within your Active Directory environment. That's the case we have here. I happen to know that the DHCP server on this network is handing out a different IP address for the DNS server than the one that's being used by my Active Directory domain.

Before I'll be able to contact the domain controller and locate the CorpNet.xyz domain, we're going to need to change that. Let's click on Edit, click the dropdown, and change this setting to Manual. Now we'll change this one from Off to On. I could just change the DNS information on this workstation, but I'm going to go ahead and configure it with a static IP address. That's just my preference. In other words, I could manually set my DNS to point to my Active Directory server and obtain the IP from the DHCP dynamically.
Let's configure the settings now. For the IP, I'll use 10.10.10.199. I know this isn't an IP that my DHCP server is handing out, so I'm safe to use it here. My subnet mask is 255.255.255.0. The gateway is my router IP address, which is 10.10.10.1. Now the DNS info, 10.10.10.5.
Remember, I pointed out a minute ago that it's very important to remember that DNS is running on the same server as Active Directory. Its IP address is 10.10.10.5. So that's the value we just put into this field. We'll click Save.
I'm going to come down to Search, type in cmd to get to a Command Prompt, use elevated privileges, and type Ipconfig /all. Note that my we can confirm that our DNS server has been changed to 10.10.10.5. That's good. All is well in the world. Now my workstation will be able to contact my domain controller in the CorpNet.xyz domain.
With that set up, we're ready to change settings and join the domain. We'll go back to System Properties. I'll mark Domain and then enter in the name of the domain that I want to join, CorpNet.xyz, and click OK.
Of course, before I can join this workstation to the domain, I have to provide the credentials of an administrative domain user. Not the local system, but an administrative user in the domain itself. That username is dfellows.
As I said earlier, we're not looking at an administrator user on this local system; we're looking at for an administrator in CorpNet.xyz. So I have to be sure to put in the right password for that user account. I'll go ahead and enter in the password for the administrator user account in my CorpNet.xyz domain. Click OK.
Everything went well. I was able to authenticate. I know that because it's welcoming me to the domain. I'll click OK. It does require the system to restart before the changes can take place. I'll click OK, and I'll Restart Now. We'll click that option and wait just a minute while the system reboots.
At this point, my system has rebooted. I have the option of logging in. I was logged in as my local user prior to joining the domain, and I can still log in as my local user after joining the domain as well. But now there's a new option available: Log in as Other user. I can now log in using a domain user account instead of a local user account.
You see, domain user accounts have a lot of advantages. For example, I could log in to this workstation using a domain user account. I could go to other workstations in the domain and log in using that very same user account. This means I don't have to duplicate my user account on every single workstation in my network that I'm going to want to log in from. If I were functioning in a workgroup situation, I would. I would have to go through and make myself a local user on each and every workstation in my network and configure that user account with the same password. That would be a pain. But by using a domain user account, I can have one user account defined in the domain and use it to log in to all of the workstations in the domain.
If you're going to log in as a domain user account, you need to log in a little bit differently. You'll note down here that it tells me that I'm going to be signing into CorpNet. So, technically, I could type dfellows right here, and it would authenticate me using the dfellows user account in the domain instead of the local user account on the local system. However, there may be times when this option is not automatically configured, or you need to sign in to another domain that's not listed here. The way you do that is to type the name of the domain first. In this example, we're going to log in to CorpNet. Then I put a backslash, and then I put in the name of the user in the domain that I want to use for authentication.
In this case, I'm going to log in as the dfellows user in the CorpNet domain. I'm essentially telling the workstation where to locate the user account I want to log in from. Because I specified that the dfellows user here resides in CorpNet, it won't use the local user account on the local system to authenticate. Instead, it'll use the dfellows user in the domain. I'll go ahead and log in with my password.
Because I'm logging in to the system for the first time using a domain user account, we need to provision that user account on this system. I have to have my profile directory set up. And I need to have my default apps installed. All of this has to happen for that domain dfellows user account on the local system. It'll take just a minute to complete.
The provisioning process is complete, so my dfellows domain user now has a profile on this local workstation.
That's it for this demonstration. In this demo, we joined a Windows workstation to a domain.

4.4.3 Managing Active Directory Objects (Demo Video)

Transcript:

In this demonstration, we're going to spend some time managing Active Directory objects.

Notice that we're going to perform these tasks from a Windows server system. I'm using the Server Manager utility on the desktop of a Windows server system. It's named DC1. This particular server system has the Active Directory Domain Services role installed, making it a domain controller. It's hosting the CorpNet.xyz domain.

To manage the objects within this domain, within Server Manager, I click Tools and then click Active Directory Users and Computers. When I do, the Active Directory Users and Computers utility is displayed.

Before we go any further, be aware that you don't have to run this utility right off of the server desktop. If you want to, you can install the necessary software, such as Windows Admin Center, on a workstation. That's beyond the scope of this demo, so we're just going to perform these tasks from the server, which is totally fine for what we're doing today.

Notice that when I initially load Active Directory Users and Computers, over here on the left, we see the name of my domain, CorpNet.xyz. As we pointed out just a second ago, that's the name of the domain that's being hosted on this domain controller.

If I expand my domain, I see a list of container objects. Container objects do just what their name implies: they contain other Active Directory objects. Their purpose is to keep things organized. Instead of putting all of our Active Directory objects within the domain, which would be really, really messy and confusing, we can sort the various objects into different containers to keep things nice, tidy, and well organized.

Notice when the name of a domain is selected over here, on the left, a list of all my container objects within the domain is displayed over here, on the right. Notice that there are several different types of container objects.

These first five container objects—Built-in, Computers, ForeignSecurityPrinciples, Manage Service Accounts, and Users—were all created by default when Active Directory was initially installed on this system. They were automatically populated with the various types of objects that they were designed to contain.

However, notice that there's another type of container object within the domain called an organizational unit. Within this domain, I have five different organizational units defined: Domain Controllers, MarketingUsers, ResearchUsers, SalesUsers, and TestUsers. With the exception of this container, Domain Controllers, these other organizational units were created by the system administrator.

The Domain Controller's organizational unit is a default container. It was created when Active Directory was initially deployed. It contains a computer account for this domain controller itself.

You might be asking, "What's the difference between an organizational unit and a container object?" Organizational units have a lot more flexibility; they can perform more functions. Container objects are very basic in nature. They're designed to hold the default objects that are created and used by Active Directory. The nice thing about these organizational units, as I've said before, is that they allow you to organize the various objects within your Active Directory domain.

There are many different approaches that you could take. One common approach is the one that I've used here, where I've defined an organizational unit for each of the divisions within my organization.

For example, I have an organizational unit for MarketingUsers. I have an organizational unit for ResearchUsers. I have an organizational unit for SalesUsers. I can put all the associated objects within Active Directory inside the appropriate container. For example, if I double-click ResearchUsers, it contains user accounts for all of the users in my company's research department.

This is one approach for creating Active Directory organizational units. But it's not the only one. Active Directory is very, very flexible. You could create different types of organizational units if you wanted.

For example, I've seen some organizations create organizational units based on geography. They might have one for North America, one unit for South America, and units for Europe, Africa, Australia, and Asia. You can configure the organizational units in whatever way works best for your organization.

For our purposes today, we're going to go with the approach that you see here, where we create a different organizational unit for each of the functional divisions within the organization. The users in Marketing, Research, and Sales are all set. Bust most organizations have more than three divisions.

If I need to create additional organizational units to support those divisions, I can click my domain, over here. Then I come over here, to this button, which allows us to create a new organizational unit. Click it, and let's create a new Organizational Unit for my Technical Support division within my company.

Note that there's an option to protect the container from accidental deletion. It's a really good idea to leave it on. It prevents the administrator from accidentally deleting the organizational unit. If you think about it, that would be really bad because the organizational unit typically contains a lot of user accounts. If you delete the organizational unit, you also automatically delete all of the user accounts within the organizational unit. If that's not what you were intending to do, that makes for a very bad day. I like to leave this option turned on. It keeps you from doing that.

Now my Technical Support organizational unit is defined. Within this organizational unit, I can create other Active Directory objects. I can create additional organizational units, meaning that I can create a hierarchical tree to reflect the structure of my organization.

For example, I can create a new organizational unit for the Help Desk group within my organization. I can also come back up here and create another organizational unit for my Backline Support group within the Technical Support division. Do you see how you can use these organizational units to mirror the structure of your company?
Within these organizational units, I can create additional Active Directory objects. The most common type of Active Directory object in an organizational unit are user accounts. These user accounts allow a given user to authenticate to the domain. They can be used to, say, log on to a workstation that's been joined to the domain.
You can also use these user accounts to control what the user is allowed to access. Basically, that user object is used to authenticate and to control access to domain resources. In other words, if a user does successfully log on to the domain, what level of access are they allowed to domain resources?
Let's suppose we need to create some user accounts for our Help Desk group. With Help Desk selected, I'll come over and click Create a New User in the current container. The first thing I need to do is provide a name. Roger is the first name, and Meinert is the last name. Then I need to provide a user logon name.
Usually, the user logon name you provide is dictated by your organization's security policy. For example, it may be something to the effect of first initial and last name. Click Next. Then we enter a password for that user. It's a bad security practice for the system administrator to know the user's password. For security purposes, only the user should know his or her password. Therefore, it's a good idea to turn this option on, User must change password at next logon. The first time the user logs on, they'll be prompted to change their password. Then you won't know what their password is.
Notice that you also have options to prevent a user from being able to change a password. You can also specify that the password never expires or that the account is disabled. These options can come in handy on occasion. Click Next. Click Finish.
Now we have a user object created in Active Directory. Let's go ahead and create a couple more. This first one will be Tom Czachor. Create the username. Click Next. Give Tom a password. Click Next and Finish. And just for practice, let's create one more: Dustin Johnson, username djohnson. Enter the password. Click Next and Finish one more time.
Now we have three user accounts for our Help Desk employees. We've talked about how to create organizational units. We've talked about how to create user accounts. You can also create group accounts using Active Directory Users and Computers. For example, we can create a group within the Help Desk organizational unit.
To do this, I'll click Create a New Group in the current container icon. Let's give it the name of Midnight Shift. This group will contain all the employees within the Help Desk that works on the midnight shift. Now we have a Midnight Shift group. To add these users to that group, we have a couple of different options. One of the easiest ways is to double-click the group, click Members, and click Add. Then enter in the users that we want to add.
First, we'll add Roger. Click OK. Click Add again. This time we'll add Tom. Type in his name and click OK. And we don't want to forget about Dustin. Let's make sure we add him. Click OK, and our three lucky midnight help desk employees are added. Click OK. Now Roger, Tom, and Dustin are all members of the Midnight Shift group.
Group accounts are really useful because, more than likely, all of the users within this group that work in the Help Desk group are going to need very similar levels of access to domain resources. Instead of going to each and every user account and making the same assignments over and over again on every user account, we can just make the assignments once, to the group, and then make all the users who need that level of access members of that group. This makes things really easy.
All right, that's all for our demo on managing Active Directory objects, specifically user objects.

4.4.4 Active Directory Facts

This lesson covers the following topics:

- Directory services
- Active Directory
- Active Directory components

Directory Services

A directory service stores information about users, computers, security groups/roles, and services. Each object in the directory has a number of attributes. The directory schema describes the types of attributes, what information they contain, and whether they are required or optional. In order for products from different vendors to be interoperable, most directory

services are based on the Lightweight Directory Access Protocol (LDAP) , which was developed from a standard called X.500.

Within an X.500-like directory, a distinguished name (DN) is a collection of attributes that define a unique identifier for any given resource. A distinguished name is made up of attribute-value pairs separated by commas. The most specific attribute is listed first, and successive attributes become progressively broader. This most specific attribute is the relative distinguished name, as it uniquely identifies the object within the context of successive (parent) attribute values.

A network directory lists the subjects (principally users, computers, and services), objects (such as directories and files) available on the network, and the permissions that subjects have over objects. A directory facilitates authentication and authorization, and it is critical that it be maintained as a highly secure service.

Active Directory

Active Directory is Microsoft's proprietary directory service. It is a centralized database that contains user accounts and security information. In a workgroup, security and management are decentralized. They occur on each computer, containing information about users and resources. With Active Directory, all computers share the same central database on a remote computer called a domain controller.

Active Directory is a hierarchical database. Hierarchical directory databases have the following advantages over a flat-file database structure:

Advantage	Description
Organization	Hierarchical databases let you sort and organize user accounts by location, function, and department.
Replication	The Active Directory database can be replicated to other systems. This eliminates the need to manually recreate user accounts on every system a user may need to access.
Delegation	Delegation allows you to assign users to manage portions of the Active Directory database without giving all users rights to the entire database. For example, you can assign an administrator to manage the sales department in North America and enable this administrator to create user accounts, remove user accounts, and change passwords. However, this sales administrator won't be allowed to access the accounting or development departments. As another example, you can enable an administrator to manage all departments in Europe but none in North America or Asia.
Scalability	A hierarchical database lets you grow the Active Directory to meet the needs of your environment.

Active Directory Components

Active Directory organizes network resources and simplifies management using the following components:

Component	Description
Domain	A domain is an administratively defined collection of network resources that share a common directory database and security policies. The domain is the basic administrative unit of an Active Directory structure. Depending on the network structure and requirements, the entire

Component	Description
	network might be represented by a single domain with millions of objects, or the network might require multiple domains.
Trees and forests	Multiple domains are grouped together in the following relationship: • A tree is a group of related domains that share the same contiguous DNS namespaces. • A forest is the highest level of the organization hierarchy and is a collection of related domain trees. The forest establishes the relationship between trees that have different DNS namespaces.
Organizational unit (OU)	An organizational unit is like a folder subdividing and organizing network resources within a domain. An organizational unit: • Is a container object. • Can hold other organizational units. • Can hold objects such as users and computers. • Can be used logically to organize network resources. • Simplifies security administration.
Generic container	Like OUs, generic containers organize Active Directory objects. Generic container objects: • Are created by default. • Cannot be moved, renamed, or deleted. • Have very few properties you can edit.
Object	Within Active Directory, each resource is identified as an object. Common objects include: • Users. • Groups. • Computers. • Shared folders. Each object contains additional information about the shared resource that can be used for locating and securing resources. Groups are composed of other directory objects with a common access level. The schema identifies the object classes (the type of objects) in the tree and the attributes (properties) of the objects. In Active Directory, each user is assigned a Security Account Manager (SAM) account name; therefore, each username must be unique.
Domain controller	A domain controller is a server that holds a copy of the Active Directory database that can be written to. Replication is copying changes to Active Directory between the domain controllers. In contrast, member servers are servers in the domain that do not have the Active Directory database.

4.4.5 Create OUs (Simulation)

Scenario

You are the IT administrator for a small corporate network. You have just installed Active Directory on a new Hyper-V guest server named CorpDC. Now, you need to create an Active Directory organizational unit (OU) structure based on the company's departmental structure.

In this lab, your task is to create the following organizational units (OUs) on the CorpDC server and ensure that each is protected from accidental deletion as follows:

- Beneath the CorpNet.local domain, create the following OUs:
  - Accounting
  - Admins
  - Marketing
  - Research-Dev
  - Servers
  - Support
  - Workstations
  - Sales
- Within the Sales OU, create the following OUs:
  - SalesManagers
  - TempSales

Explanation

While completing this lab, use the following information:

- Beneath the CorpNet.local domain, create the following OUs:
  - Accounting
  - Admins
  - Marketing
  - Research-Dev
  - Servers
  - Support
  - Workstations
  - Sales
- Beneath the Sales OU, create the following OUs:
  - SalesManagers
  - TempSales

Complete this lab as follows:

1. Access the CorpDC server.
   a. From the left pane of Hyper-V Manager, select **CORPSERVER** .
   b. From the Virtual Machines pane, double-click **CorpDC** .
2. Create the Active Directory organizational units (OUs) beneath the CorpNet.local domain.
   a. From the Server Manager's menu bar, select **Tools** > **Active Directory Users and Computers** .
   b. From the left pane, right-click **CorpNet.local** and then select **New** > **Organizational Unit** .

      You can also create OUs by selecting the **Create a new organizational unit in the current container** icon ( ) located in the Active Directory Users and Computers ribbon.

   c. Enter the ***name*** of the OU to be created.
   d. Ensure that **Protect container from accidental deletion** is selected and then select **OK** .
   e. Repeat steps 2b - 2d until all the required domain OUs are created.
3. Create the OUs within the Sales OU.

a. From the left pane, select **CorpNet.local** > **Sales** .
b. From the menu bar, select the **Create a new organizational unit in the current container** icon.
c. Enter the ***name*** of the OU to be created.
d. Ensure that **Protect container from accidental deletion** is selected and then select **OK** .
e. Repeat steps 3a - 3d to create the remaining OU.

4.4.6 Delete OUs (Simulation)

Scenario

You are the IT administrator for a corporate network. You have just installed Active Directory on a new Hyper-V guest server named CorpDC. You have created an Active Directory structure based on the company's departmental structure. While creating the structure, you added a Workstations OU in each of the departmental OUs. After further thought, you decide to use one Workstations OU for the entire company. As a result, you need to delete the departmental Workstations OUs.

In this lab, your task is to delete the following OUs on CorpDC:

- Within the **Marketing** OU, delete the **Workstations** OU.
- Within the **Research-Dev** OU, delete the **Workstations** OU.
- Within the **Sales** OU, delete the **Workstations** OU.

Explanation

To complete this lab, you need to delete the following OUs on CorpDC:

- Within the **Marketing** OU, delete the **Workstations** OU.
- Within the **Research-Dev** OU, delete the **Workstations** OU.
- Within the **Sales** OU, delete the **Workstations** OU.

Complete this lab as follows:

1. Access the CorpDC server.
   a. From Hyper-V Manager, select **CORPSERVER** .
   b. From the Virtual Machines pane, double-click **CorpDC** .
2. Delete the applicable OUs.
   a. From Server Manager, select **Tools** > **Active Directory Users and Computers** .
   b. Select **View** > **Advanced Features.**
   This enables the Advanced feature, allowing you to disable the OU from accidental deletion.
   c. From the left pane, expand **CorpNet.local** > ***the_parent OU*** .
   d. Right-click the ***OU*** that needs to be deleted and then select **Properties** .
   e. Select the **Object** tab.
   f. Clear **Protect object from accidental deletion** and then select **OK** .
   g. Right-click the ***OU*** to be deleted and then select **Delete** .
   h. Select **Yes** to confirm the OU's deletion.
   i. Repeat steps 2c - 2h to delete the remaining OUs.
3. From the *Active Directory Users and Computers* menu bar, select **View** > **Advanced Features** to turn off the Advanced Features view.

4.4.7 Group Policy (Lesson Video)

Transcript:

One of the great benefits of managing your networks with a domain is that a domain lets you apply various configuration settings such as security settings globally. You can use a Group Policy to configure settings across multiple Windows hosts in a domain.

In this lesson, we're going to spend some time looking at what Microsoft's Group Policy is and how it works.
Let's first explain just what a policy is.
A policy is a set of configuration settings that can be used to control the working environment of user accounts and computer accounts.
These settings can be applied in one of two ways.
First, an administrator could go to each computer and configure user and computer policies manually using the Local Group Policy Editor.
The disadvantage of using this method is that it takes a lot of time going from computer to computer and increases the possibility of user error.
Because of this, this method is typically only used for small networks that don't use Active Directory, or AD.
The better method for you to apply Group Polices is to configure and apply them using Active Directory's Group Policy Management.
Using this method, you're able to push down the needed configuration settings to the individual hosts within the domain straight from the domain controller.
As you can imagine, making the change once to a domain controller is a lot easier than going from computer to computer creating the same setting over and over.
It also means that you're less likely to make a mistake.
It's important to keep in mind that it's possible to use both local and domain policies at the same time.
But, if there's a conflict between the two, the domain policy will always take precedence over any local settings.
When using Group Policy, policies are grouped together in a collection and stored in a Group Policy object, or GPO.
Because GPOs contain a collection of settings, they're very powerful and you can use them to apply a number of things.
For example: registry settings, running scripts, applying templates, setting up software, making configuration settings, and more.
Here you see we're editing the GPO named Default Domain Policy, and notice that within this policy in the left panel we have a tree structure, in which we've stored our Group Policy settings.
In this example, if extend our tree out to the bottom, we go from: Computer Configuration to Policies; then to Windows Settings, to Security Settings, to Account Policies; and within Account Policies, we have a group of policies that are related to passwords.
If we click here within Password Policies, we have the group of policies as shown.
Notice that with these policies we can enforce such things as the password history.
Each policy will include some settings, and those can be seen here.
Double-clicking on one of these policies lets you configure these settings.
In the example seen here, Enforce password history is enabled and 24 passwords will be remembered. This means that the end user must use 24 unique passwords before they'll be allowed to reuse a password that they've used before.
As another example, you'll notice we also have a policy for setting the maximum password age. In other words, how many days the user can use the same password before they'll be forced to change it.
Right now, that's set to 42 days.
We also have additional policies to determine the password age, the password length, and whether passwords must comply with our complexity requirements.
As you can see, each of these individual policies lets us customize exactly how we want to manage our passwords.
Policies within a Group Policy object, such as the Default Domain Policy shown here, are divided into two different categories Computer Configuration and User Configuration.
You might be asking what the difference is between a Computer Configuration Policy and a User Configuration Policy.
A Computer Configuration Policy is applied to the computer itself. Those settings will be applied no matter who logs on to the computer. In other words, Group Policy doesn't care who the individual user is only which computer they're using.
The types of computer policies you may see under Computer Configuration include such things as: policies to control what software should be installed on the computer; scripts that might need to be run when the system boots or shuts down; password restrictions that are going to be applied to all the user accounts on the system; and also network security settings or registry settings that are going to be applied to the entire computer.

The important thing to remember about Computer Configuration Policies is that they're applied as the system boots up and initially connects to the domain. The system enforces them before any user logs on.
User Configuration Policies, on the other hand, are applied to a specific user. This means that a user's polices will still be applied regardless of which computer they use to log on to the domain.
As such, different policies can be set for different users. For example, you may have one computer system being used by three different users.
Taking advantage of user policies, you can apply different settings based upon the User Configuration Policy that you set up for individual users.
Some sample User Policy settings could include the software that's installed for a specific user, or scripts that run when they log on or log off.
It might also include security settings for your web browser. You could even use it to push down a list of favorites you've already selected for your browser.
You can also use it to push down registry settings that apply just to that individual user.
Just remember that the key difference between User Policies and Computer Policies is the that User Policies are applied on a per-user basis. So, they're not applied until the user logs on.
Computer Configuration Policies, on the other hand, are applied to the entire computer system no matter who logs on. So they're applied when the system initially boots up.
There are literally hundreds of different configuration settings that can be applied through Group Policy, and we can't possibly cover all of them here. But, there are a few key ones that you should be familiar with.
First, we have Account Policies. We use Account Policies to control such things as password settings, account lock out settings, Kerberos settings, and more.
Next, we have Local Policies/Audit Policy. You use the Audit Policy settings to configure auditing for various events such as log on, account management, or privileged use.
Next, we have Local Policies/User Rights assignment. User Rights determine what actions a given user can perform on a given computer.
We also have Local Policies/Security Policies. Security Policies are used to control such things as allowing a user to install an unsigned driver or requiring control-alt-delete to be pressed in order to log on.
We can also configure Registry Policies. You can use Registry Policies to configure specific registry keys and values. They can also specify whether you can read or even change a specific registry value.
Another set of Group Policies affect the file system. You can use File System Policies to configure file and folder permissions that apply to multiple computers.
We also have Software Restriction Policies. You can use Software Restriction Policies to define what software can run on any computer that's joined to the domain. These Software Restriction Policies can be applied to a specific user or they can be applied globally to all users.
Finally, we have administrative templates.
Administrative templates are registry-based settings that you can configure within a Group Policy object. They're very useful. You can forgo editing the registry or making configuration changes in Control Panel or the Settings app individually on every single computer in your network. Instead, just use the settings under administrative templates within Group Policy to control the computer configuration and centrally manage the user experience.
For example, you can use administrative templates to enable and configure various Windows features such as Bitlocker, offline files, or even parental controls.
You can also use administrative templates to do fun things like customize the start menu, customize the task bar, or even set up the desktop environment.
That's it for this lesson.
In this video, we talked about Group Policy management.
We first talked about what Group Policy is and how policies can be used to push down configuration settings to all the computers in your domain.
We talked about the relationship between Group Policy and Local Policy settings that you can configure on individual machines.
We then looked at the difference between Computer Configuration Policies and User Configuration Policies.
And then we ended this lesson by reviewing a list of policies that you should be familiar with in order to effectively manage a domain.

4.4.8 Use Group Policy (Demo Video)

Transcript:

In this demonstration, we're going to spend some time working with Group Policy. Group Policy contains a myriad of settings that you can use to control the way Windows looks, runs, and behaves.

Understand that there are two different sets of Group Policy settings for Windows. If your Windows system isn't a part of a domain, the locally stored Group Policy settings are applied. But if your system is a member of a domain, you can also apply Group Policy settings from a domain controller.

Let's begin by looking at the first option. To start, I'm going to come down here and click on Search. Then I'm going to type in gpedit.msc and press Enter to run the Group Policy Editor.

You'll notice up in the window's title bar that it says Local Group Policy Editor. That word Local is key. This tells me that the settings I'm configuring are just for this computer system. You'll also notice that there are two kinds of settings. We have Computer Configuration, and we have User Configuration.

A Computer Configuration Group Policy is applied when the system first boots up, and it's applied to every single user who logs in. The User Configuration settings are different. They're applied on a per-user basis, and they're applied only when the user logs in.

Let's take a look at some sample Computer Configuration settings. We'll go to Administrative Templates > Windows Components and then to Store. Within the Store set of Group Policy settings, you can see each individual setting here. For example, there's one here that turns off the Store Application. I'll double-click it. When I do, I can look down here in Help, and it tells me what this setting does. Basically, this either allows or denies access to the Windows Store application. If this system is being used in a company environment, you might not want your users going out and downloading whichever apps they want from the Windows Store. In this situation, you could turn Store access off by clicking Enabled and OK.

Now the policy is enabled, but my Store icon is still available on the taskbar. I could still go out to the Windows Store because this change won't be applied until the system shuts down and reboots again. That's because it's a computer policy. Okay, let's go ahead and close this.

Now let's go down here under User Configuration and expand Administrative Templates. Then let's click Control Panel. There are many different Group Policy settings we can configure here that affect the way the user interacts with Control Panel.

Remember that the user settings aren't applied until the user actually logs in. For example, we could come over here and say, "You know what, I don't want my users having any access to Control Panel or to my Settings app." Your average user could really mess things up if they don't know what they're doing.

So what we want to do is go in and turn access completely off. We're going to enable this policy. It tells us down here that, once enabled, if a user tries to select a Control Panel item, a message will appear explaining that this action isn't allowed. The next time somebody logs in to this system, they'll no longer have access to Control Panel.

So that's one way that you can apply Group Policy settings—with the Local Group Policy Editor. This works fine if you're on a network of three, four, or five Windows systems. But you'd still have to go from system to system to make all the changes. If you're in a big network with thousands of computers, this isn't a good way to do things.

A better way is to configure your Group Policy settings on a domain controller. Using a domain controller, you can make configuration changes like we just did here, but all at once for everyone. They'll automatically be pushed down to each individual Windows system that's a member of the domain. We can't make those changes here from a workstation, though. Instead, we have to switch over and go to the domain controller server itself. Let's do that.

Alright, I'm at my DC1 domain controller. I can come over here to Tools and click Group Policy Management. When I do, I can browse down through my domain to the Group Policy Object that I want to manage. I right-click and click Edit. This is the Default Domain Policy. It's configured by default as soon as I set up Active Directory, and it'll be applied by default to all Windows systems that are members of the domain unless I tell it not to.

You'll notice that Domain Group Policy is divided up basically the same way as the Local Group Policy. You have your Computer Policies and your User Policies. It works in the exact same way, too—Computer Policies are applied as soon as the system comes online, and User Policies are applied when the user logs in.

Again, the nice thing is that the changes I make on the domain controller will be applied to all the Windows systems that are members of that domain. For example, let's go into my Computer Configuration > Windows Settings > Security Settings > Account Policies and then to Account Lockout Policy.

The Account Lockout Policy is used to prevent an attacker from trying to guess passwords on the system. It does this by saying, "You know what, you're allowed to enter the wrong password a limited number of times. Once you exceed that number, I'm going to lock the system because the authorized user is probably not going to take that many attempts to log in to their own system."

And let's come down here to Account lockout threshold. You'll notice that by default, Account Lockout Policy is disabled. You can try as many passwords as you want, and the system won't lock you out. That's not a good thing. It allows an attacker to just sit there at the console and try password after password until they get the right one.
So let's say that if you can't get the right password after three attempts, we're going to assume that you're not the right person and lock the system. Click OK. When I do, it says, "You know what, if we're going to do that, we need to change the values of these other Group Policy settings as well." These are things like how long we're going to keep the system locked and how long we're going to wait before we reset the counter that's recording the number of invalid login attempts.
So now I'm going to give the user 3 chances to log in, and it's going to stay locked for 30 minutes. After 30 minutes, we'll reset the lockout counter. And because it's a Computer Configuration, the next time each domain system powers on and connects, the setting will be automatically pushed down to them. I don't have to walk around from system to system. Making changes just once is really convenient.
Okay, that's it for this demonstration. In this demo, we configured Group Policy settings.

4.4.9 Group Policy Facts

This lesson covers the following topics:

- Group Policy
- GPO structure

Group Policy

A policy is a set of configuration settings applied to users or computers. Group policies allow the administrator to apply multiple settings to multiple objects within the Active Directory domain at one time. A set or collection of Group Policy configurations is called a Group Policy Object (GPO). The GPO is a collection of files that includes registry settings, scripts, templates, and software-specific configuration values.

GPO Structure

Each GPO has a common structure with hundreds of configuration settings that can be enabled and configured. Settings are divided into two categories:

GPO Category	Description
Computer Configuration	Computer policies are enforced for the entire computer and are initially applied when the computer boots. Computer policies are in effect regardless of the user logging into the computer. Computer policies include: • Software that should be installed on a specific computer • Scripts that should run at startup or shutdown • Password restrictions that must be met for all user accounts • Network communication security settings • Registry settings that apply to the computer (the HKEY_LOCAL_MACHINE subtree) Computer policies also include a special category of policies called user rights. User rights identify system maintenance tasks and the users or groups who can perform these actions. Actions include: • Changing the system time

	• Loading and unloading device drivers • Removing a computer from a docking station • Shutting down the system Computer policies are initially applied as the computer boots and are enforced before any user logs on.
User Configuration	User policies are enforced for specific users and are applied when the user logs on. User Policy settings include: • Software that should be installed for a specific user • Scripts that should run at logon or logoff • Internet Explorer user settings (such as favorites and security settings) • Registry settings that apply to the current user (the HKEY_CURRENT_USER subtree) User policies are initially applied as the user logs on and customizes Windows based on his or her preferences.

GPOs apply to objects when they are linked to containers and configured with specific settings.

- GPOs can be linked to Active Directory domains or organizational units (OUs).
- Built-in containers (such as the Computers container) and folders cannot have GPOs linked to them.
- A GPO applied to an OU affects only the users and computers in that OU.
- A GPO applied to a domain affects all users and computers in all OUs in that domain.
- A local GPO is stored on a local machine. It can be used to define settings even if the computer is not connected to a network.
- A specific setting in a GPO can be:
    - Undefined - this means that the GPO has no value for that setting and does not change the current setting.
    - Defined - this means that the GPO identifies a value to enforce.
- GPOs are applied in the following order:

1. The Local Group Policy on the computer.
2. GPOs linked to the site.
3. GPOs linked to the domain that contains the User or Computer object.
4. GPOs linked to the organizational unit(s) that contain(s) the User or Computer object (from the highest-level OU to the lowest-level OU).

Use the acronym LSDOU (Local, Site, Domain, and OU) to help you remember the order that GPOs are applied. The local policy is always applied, but it may be overwritten by a policy from Active Directory.

- Individual settings within all GPOs are combined to form the effective Group Policy setting as follows:
    - If a setting is defined in one GPO and undefined in another, the defined setting is enforced (regardless of the position of the GPO in the application order).
    - If a setting is configured in two GPOs, the setting in the last-applied GPO is used.

4.4.10 Create and Link a GPO (Simulation)

Scenario

You are the IT security administrator for a small corporate network. You would like to use Group Policy to enforce settings for certain workstations on your network. You have prepared and tested a security template file that contains policies that meet your company's requirements.

In this lab, your task is to perform the following on CorpDC:

- Create a GPO named **Workstation Settings** in the CorpNet.local domain.
- Link the Workstation Settings GPO to the following organizational units (OUs):
    - **Marketing** > **TempMarketing**
    - **Sales** > **TempSales**
    - **Support**
- Import the **ws_sec.inf** template file located in C:\Templates to the Workstation Settings Group Policy object.

Explanation

While completing this lab, use the following information:

- Link the Workstation Settings GPO to the following organizational units (OUs):
    - **Marketing** > **TempMarketing**
    - **Sales** > **TempSales**
    - **Support**
- Import the **ws_sec.inf** template file located in **C:\Templates** .

Complete this lab as follows:

1. Access the CorpNet.local domain.
    a. From Server Manager, select **Tools** > **Group Policy Management** .
    b. Expand **Forest: CorpNet.local** > **Domains** > **CorpNet.local** .
    c. Maximize the window for better viewing.
2. Create the Workstation Settings GPO and link it to the CorpNet.local domain.
    a. Right-click the **Group Policy Objects** OU and select **New** .
    b. In the Name field, use **Workstation Settings** and then select **OK** .
3. Link OUs to the Workstation Settings GPO.
    a. Right-click the ***OU*** and select **Link an Existing GPO** .
    b. Under Group Policy Objects, select **Workstation Settings** from the list and then select **OK** .
    c. Repeat steps 3a-3b to link the additional OUs.
4. Import the ws_sec.inf security policy template.
    a. Expand **Group Policy Objects** .
    b. Right-click **Workstation Settings** and select **Edit** .
    c. Under Computer Configuration, expand **Policies** > **Windows Settings** .
    d. Right-click **Security Settings** and select **Import Policy** .
    e. Browse to **C:\Templates** .
    f. Select **ws_sec.inf** and then select **Open** .

4.4.11 Create User Accounts (Simulation)

Scenario

You are the IT administrator for a small corporate network. You recently added an Active Directory domain to the CorpDC server to manage network resources centrally. You now need to add user accounts in the domain.

In this lab, your task is to create the following user accounts on CorpDC:

User	Job Role	Departmental OU
Juan Suarez	Marketing manager	Marketing\MarketingManagers
Susan Smith	Permanent sales employee	Sales\PermSales
Mark Burnes	Sales manager	Sales\SalesManagers
Borey Chan	Temporary sales employee	Sales\TempSales

Use the following user account naming standards and specifications as you create each account:

- Create the user account in the departmental OU corresponding to the employee's job role.
- User account name: ***First name*** + ***Last name***
- Logon name: ***firstinitial*** + ***lastname*** with **@CorpNet.local** as the domain
- Original password: **asdf1234$** (must change after the first logon)
- Configure the following for the temporary sales employee:
    - Limit the logon hours to allow logon only from **8:00 a.m.** to **5:00 p.m.** , **Monday** through **Friday** .
    - Set the user account to expire on **December 31st** of the current year.

Explanation

Use the following user account specifications as you create each account.

User	Job Role	Departmental OU
Juan Suarez	Marketing manager	Marketing\MarketingManagers
Susan Smith	Permanent sales employee	Sales\PermSales
Mark Burnes	Sales manager	Sales\SalesManagers
Borey Chan	Temporary sales employee	Sales\TempSales

Complete this lab as follows:

1. Access Active Directory Users and Computers on the CorpDC server.
    a. From Hyper-V Manager, select **CORPSERVER** .
    b. From the Virtual Machines pane, double-click **CorpDC** .
    c. From the Server Manager's menu bar, select **Tools** > **Active Directory Users and Computers** .
    d. Maximize the window for better viewing.

2. Create the domain user accounts.
    a. From the left pane, expand **CorpNet.local** .
    b. Browse to the appropriate ***OU*** .
    c. Right-click the ***OU*** and select **New** > **User** .
    d. In the *First name* field, enter the user's ***first name*** .
    e. In the *Last name* field, enter the user's ***last name*** .
    f. In the User logon name field, enter the user's ***logon name*** , which should be the first letter of the user's first name together with their last name *(e.g., jsuarez).*

        The domain @CorpNet.local is appended automatically to the end of the logon name.

    g. Select **Next** .
    h. In the *Password field* , enter **asdf1234$** .
    i. In the *Confirm password* field, enter **asdf1234$** .
    j. Ensure **User must change password at next logon** is selected and then select **Next** .
    k. Select **Finish** to create the object.
    l. Repeat steps 2b–2k to create the additional users.
3. Modify user account restrictions for the temporary sales employee.
    a. Right-click **Borey Chan** and select **Properties** .
    b. Select the **Account** tab.
    c. Select **Logon hours** .
    d. From the Logon Hours dialog, select **Logon Denied** to clear the allowed logon hours.
    e. Select the time range of **8:00 a.m.** to **5:00 p.m.** , **Monday** through **Friday** .
    f. Select **Logon Permitted** to allow logon.
    g. Select **OK** .
    h. Under Account expires, select **End of** .
    i. In the *End of* field, use the drop-down calendar to select **31 December** of the ***current year*** .
    j. Select **OK** .

4.4.12 Manage User Accounts (Simulation)

Scenario

You are the IT administrator for a small corporate network. You recently added an Active Directory domain on the CorpDC server to manage network resources centrally. Organizational units in the domain represent departments. User and computer accounts are in their respective departmental OUs.

Over the past few days, several personnel changes have occurred that require changes to user accounts.

In this lab, your task is to use the following information to make the necessary user account changes on CorpDC:

- Mary Barnes from the Accounting Department has forgotten her password, and now her account is locked.
    - Unlock the account.
    - Reset the password to **asdf1234$**
    - Require a password change at the next logon.
- Mark Woods has been fired from the accounting department. Disable his account.
- Pat Benton is returning to the Research-Dev department from maternity leave. Her account is disabled to prevent logon. Enable her account.
- Andrea Simmons from the Research-Dev department has recently married.
    - Rename the account **Andrea Socko** .
    - Change the last name to **Socko** .
    - Change the display name to **Andrea Socko** .
    - Change the user logon and the pre-Windows 2000 user logon name to **asocko** .

- For all users in the Support OU (but not the SupportManagers OU), allow logon only to the Support computer.

Explanation

Complete this lab as follows:

1. Access Active Directory Users and Computers on the CorpDC server.
    a. From the Server Manager's menu bar, select **Tools** > **Active Directory Users and Computers** .
    b. Maximize the window for better viewing.
2. Unlock the Mary Barnes account.
    a. From the left pane, expand and select **CorpNet.local** > **Accounting** .
    b. Right-click **Mary Barnes** and select **Reset Password** .
    c. In the New password field, enter **asdf1234$** .
    d. In the Confirm password field, enter **asdf1234$** .
    e. Make sure **User must change password at next logon** is selected.
    f. Make sure **Unlock the user's account** is selected.
    g. Select **OK** .
    h. Select **OK** to confirm the change.
3. Disable the Mark Woods account.
    a. Right-click **Mark Woods** and select **Disable Account** .
    b. Select **OK** to confirm the change.
4. Enable Pat Benton's account.
    a. From the left pane, select **Research-Dev** .
    b. From the right pane, right-click **Pat Benton** and select **Enable Account** .
    c. Select **OK** to confirm the change.
5. Rename the Andrea Simmons account.
    a. Right-click **Andrea Simmons** and select **Rename** .
    b. Enter **Andrea Socko** and press **Enter** . This opens the Rename User dialog.
    c. In the Last name field, enter **Socko** .
    d. In the User logon name field, replace the old name with **asocko** .
    e. Select **OK** .
6. Configure user account restrictions.
    a. From the left pane, select **Support** .
    b. Press the **Ctrl** key, and then from the right pane, select both the **Janice Rons** and **Tom Plask** users to edit multiple users at the same time.

        In Safari, press **Command** and select each user.

    c. Right-click the ***user accounts*** and select **Properties** .
    d. Select the **Account** tab.
    e. Select **Computer restrictions** .
    f. Select **Log On To** .
    g. Select **The following computers** .
    h. In the Computer name field, type **Support** .
    i. Select **Add** .
    j. Select **OK** .
    k. Select **OK** .

4.4.13 Create a Group (Simulation)

Scenario

You are the IT administrator for the CorpNet domain. You have decided to use groups to simplify the administration of access control lists. Specifically, you want to create a group containing the department managers.

In this lab, your task is to use Active Directory Users and Computers to complete the following actions on the CorpDC server:

- In the Users container, create a group named **Managers** . Configure the group as follows:
  - Group scope: **Global**
  - Group type: **Security**
- Make the following users members of the Managers group:
-

Organization Unit	Username
Accounting	**Mark Woods**
Research-Dev	**Pat Benton**
Marketing\MarketingManagers	**Juan Suarez**
Research-Dev\ResearchManagers	**Arlene Kimbly**
Sales\SalesManagers	**Mark Burnes**
Support\SupportManagers	**Shelly Emery**

Explanation

Complete this lab as follows:

1. Access Active Directory Users and Computers on the CorpDC server.
   a. From the Server Manager's menu bar, select **Tools** > **Active Directory Users and Computers** .
   b. Maximize the window for better viewing.
2. In the Users container, create a group named **Managers** .
   a. From the left pane, expand and select **CorpNet.local** > **Users** .
   b. Right-click the **Users** container and select **New** > **Group** .

      You can also create a new group by selecting the Create a new group in the current container icon found in the ribbon.

   c. In the *Group name* field, enter **Managers** .
      A pre-Windows 2000 group name is created automatically but can be changed.
   d. Under Group scope, make sure **Global** is selected.
   e. Under Group type, make sure **Security** is selected and select **OK** .
3. Add user accounts to the Managers group.
   a. From the left pane, ensure that the Users container is still selected.
   b. From the right pane, right-click **Managers** and select **Properties** .

c. Select the **Members** tab.
d. Select **Add** .
e. In the *Enter the object names to select* field, enter all the ***usernames* .** Use a semicolon to separate each name.
   Example: Steve Hoffer; Peter Williams; Princess Diana
f. Select **Check Names** .
g. Select **OK** to add the users and close the dialog.
h. Select **OK** to close the Managers Properties dialog.

You can also add individual users to a group by right-clicking the user and selecting **Add to a group** .

4.4.14 Create Global Groups (Simulation)

Scenario

You are the IT Administrator for the CorpNet.local domain. You are in the process of implementing a group strategy for your network. You have decided to create global groups as shadow groups for specific departments in your organization. Each global group will contain all users in the corresponding department.

In this lab, your task is to:

- Create the following global security groups on the CorpDC server in their corresponding OUs:

OU Creation Location	New Group Name
Accounting	Accounting
Research-Dev	Research-Dev
Sales	Sales

- Add all user accounts in the corresponding OUs and sub-OUs as members of the newly created groups.

Explanation

While completing this lab, use the following information:

OU Creation Location	New Group Name
Accounting	Accounting
Research-Dev	Research-Dev

Sales	Sales

Complete this lab as follows:

1. Access Active Directory Users and Computers on the CorpDC server.
    a. From the Server Manager's menu bar, select **Tools** > **Active Directory Users and Computers** .
    b. Maximize the window for better viewing.
    c. From the left pane, expand **CorpNet.local** .
2. Create the groups.
    a. Right-click the **OU** where the new group is to be added and select **New** > **Group** .
    b. In the *Group name* field, enter the **name** of the group.
    c. Make sure the **Global** *Group scope* is selected.
    d. Make sure the **Security** *Group type* is selected.
    e. Select **OK** .
3. Add users to groups.
    a. In the right pane, right-click the ***user account(s)*** and select **Add to a group** . (Use the Ctrl or Shift keys to select and add multiple user accounts to a group at one time.)
    b. In the *Enter the object names to select* field, enter the **name** of the group.
    c. Select **Check Names** and verify that the object name was found.
    d. Select **OK** to accept the groups added.
    e. Select **OK** to acknowledge the change.
    f. If a sub-OU with users exists, double-click on the sub-OU and then repeat step 3. Do this for each sub-group.
4. Repeat steps 2 - 3 for additional groups and users.

4.4.15 Practice Questions (Section Quiz)

q_actdir_ad_01_secp8

What is the name of the service included with the Windows Server operating system that manages a centralized database containing user account and security information?

Answers:

- Active Directory
- Active directory
- active directory
- AD
- ad

Explanation:

Active Directory (AD) is a centralized database that is included with the Windows Server operating system. Active Directory is used to store information about a network. It stores such things as user accounts, computers, printers, and security policies.

q_actdir_ad_02_secp8

Match each Active Directory term on the left with its corresponding definition on the right.

Answers:

- Tree
- Forest
- Domain
- Organizational unit
- Object

Explanation:

The Active Directory structure includes the following components:

- A tree is a group of related domains that share the same contiguous DNS namespace.
- A forest is a collection of related domain trees.
- A domain is an administratively defined collection of network resources that share security policies and a common directory database.
- An organizational unit (OU) is like a folder. An OU subdivides and organizes network resources within a domain.
- An object is a network resource as identified within Active Directory.

q_actdir_ad_advantages_secp8

Which of the following are advantages of using hierarchical databases like Active Directory? (Select two.)

Answers:

- They allow for decentralized security and management.
- ***They enable replication of the database to other systems.**
- They limit the growth of the Active Directory to meet the needs of your environment.
- ***They allow for organization of user accounts by location, function, and department.**
- They require manual recreation of user accounts on every system a user may need to access.

Explanation:

The following are advantages of using hierarchal databases like Active Directory:

- They enable replication of the database to other systems. Explanation: hierarchical databases like Active Directory can replicate the database to other systems, eliminating the need to manually recreate user accounts on every system a user may need to access.
- They allow for organization of user accounts by location, function, and department. Explanation: hierarchical databases let you sort and organize user accounts by location, function, and department, providing a structured and organized approach to managing user accounts.

The following are not advantages of using hierarchal databases like Active Directory:

- They allow for decentralized security and management. One of the key advantages of hierarchical databases like Active Directory is that they provide centralized security and management, not decentralized.
- They limit the growth of the Active Directory to meet the needs of your environment. Hierarchical databases like Active Directory are scalable, meaning they allow for growth to meet the needs of your environment, not limit it.
- They require manual recreation of user accounts on every system a user may need to access. One of the key advantages of hierarchical databases like Active Directory is that they can replicate the database to other systems, eliminating the need for manual recreation of user accounts.

q_actdir_centralized_database_secp8

What is the primary function of Active Directory as a centralized database in a network?

Answers:

- ***It stores and organizes all user accounts and security information.**
- It provides internet access to all computers in the network.
- It serves as a backup system for all files in the network.
- It manages the power supply to all computers in the network.

Explanation:

Active Directory is Microsoft's proprietary directory service. It is a centralized database that contains user accounts and security information. In a workgroup, security and management are decentralized. They occur on each computer, containing information about users and resources. With Active Directory, all computers share the same central database on a remote computer called a domain controller.

While Active Directory can manage certain network services, providing internet access is not its primary function. This is typically handled by network routers and switches.

Active Directory does not serve as a backup system for all files in the network. Its primary function is to manage user accounts and security information. Backup systems are separate and are used to store copies of data that can be restored in the event of data loss.

Active Directory does not manage the power supply to all computers in the network. Its primary function is to manage user accounts and security information. Power management is typically handled by each individual computer's operating system and hardware.

q_actdir_domain_controller_secp8

Which of the following BEST describes the domain controller component of Active Directory?

Answers:

- ***A domain controller is a server that holds a copy of the Active Directory database that can be written to and is responsible for copying changes to Active Directory between the domain controllers.**
- A domain controller is a user account that has administrative privileges to manage the Active Directory database.
- A domain controller is a specific type of network resource within a domain.
- A domain controller is a software application that manages the replication of the Active Directory database.
- A domain controller is a physical device that connects the network to the Active Directory database.

Explanation:

A domain controller is a server that holds a writable copy of the Active Directory database. It is responsible for managing changes to the database and replicating these changes to other domain controllers to ensure consistency across the network.

A domain controller is not a user account, but a server that manages the Active Directory database.

A domain controller is not a type of network resource, but a server that manages the Active Directory database.

While software is involved in the process, a domain controller is not a software application but a server that holds a copy of the Active Directory database.

A domain controller is not just a physical device that connects the network to the Active Directory database, but a server that holds a writable copy of the Active Directory database and manages changes to it.

q_actdir_domain_grouping_secp8

A large multinational corporation has multiple domains that share the same contiguous DNS namespaces, as well as domains with different DNS namespaces. The IT department is tasked with organizing these domains.

Which of the following options best describes how the domains should be grouped?

Answers:

- All domains should be grouped into a single tree, regardless of their DNS namespaces.
- ***Domains with the same contiguous DNS namespaces should be grouped into a tree, and all trees should be grouped into a forest.**
- Domains with different DNS namespaces should be grouped into a tree, and all trees should be grouped into a forest.
- Domains with the same contiguous DNS namespaces should be grouped into a forest, and all forests should be grouped into a tree.
- All domains should be grouped into a single forest, regardless of their DNS namespaces.

Explanation:

Domains with the same contiguous DNS namespaces should be grouped into a tree, and all trees should be grouped into a forest. In Active Directory, a tree is a group of related domains that share the same contiguous DNS namespaces. A forest, on the other hand, is the highest level of the organization hierarchy and is a collection of related domain trees. The forest establishes the relationship between trees that have different DNS namespaces.

The following are incorrect answers:

- All domains should be grouped into a single tree, regardless of their DNS namespaces. This is incorrect because a tree in Active Directory is a group of related domains that share the same contiguous DNS namespaces. Domains with different DNS namespaces should not be grouped into the same tree.
- Domains with different DNS namespaces should be grouped into a tree, and all trees should be grouped into a forest. This is incorrect because a tree in Active Directory is a group of related domains that share the same contiguous DNS namespaces. Domains with different DNS namespaces should not be grouped into the same tree.
- Domains with the same contiguous DNS namespaces should be grouped into a forest, and all forests should be grouped into a tree. This is incorrect because a forest in Active Directory is a collection of related domain trees, not the other way around.
- All domains should be grouped into a single forest, regardless of their DNS namespaces. This is incorrect because while a forest can contain multiple trees with different DNS namespaces, it is not necessary or always beneficial to group all domains into a single forest. The organization of domains into trees and forests should be based on the specific needs and structure of the organization.

q_actdir_generic_containers_secp8

Which of the following statements correctly describe the characteristics of generic containers in Active Directory? (Select two.)

Answers:

- Generic containers can be moved, renamed, or deleted.
- ***Generic containers are created by default.**

- Generic containers have numerous properties you can edit.
- Generic containers cannot hold other organizational units.
- ***Generic containers are used to organize Active Directory objects.**

Explanation:

The following are statements that correctly describe generic containers:

- Generic containers are created by default in Active Directory.
- Generic containers are used to organize Active Directory objects. Like organizational units, generic containers are used to organize Active Directory objects.

The following are incorrect statements describing generic containers:

- Generic containers can be moved, renamed, or deleted.
- Generic containers have numerous properties you can edit. Generic containers have very few properties you can edit.
- Generic containers cannot hold other organizational units. While it's true that generic containers are different from organizational units, the statement is misleading because it suggests that generic containers cannot contain other objects, which is not true. Generic containers can contain other Active Directory objects, just like organizational units.

q_actdir_hierarchal_secp8

What is one of the main advantages of Active Directory being a hierarchical database?

Answers:

- It allows for faster internet speeds.
- ***It allows for organization and sorting of user accounts and resources.**
- It allows for automatic software updates.
- It allows for increased storage capacity.

Explanation:

One of the main advantages of Active Directory being a hierarchical database is that it allows for the organization and sorting of user accounts and resources. This can be done by location, function, department, or any other criteria that suits the needs of the organization.

The hierarchical nature of Active Directory does not directly impact internet speeds. Internet speeds are typically determined by the network infrastructure and internet service provider.

While Active Directory can be used to manage software updates, this is not a direct result of it being a hierarchical database. Software updates are typically managed through specific services or tools, such as Windows Server Update Services (WSUS).

The hierarchical nature of Active Directory does not increase storage capacity. Storage capacity is determined by the physical storage hardware and the file system in use.

q_actdir_schema_secp8

A new IT administrator is tasked with managing Active Directory for their company. The administrator needs to understand the types of objects in the tree and the properties of these objects.

Which of the following BEST describes the Active Directory component that the new administrator needs to understand?

Answers:

- The administrator needs to understand the domain controller, as it manages the Active Directory database.
- ***The administrator needs to understand the schema, as it identifies the object classes and their attributes in the tree.**
- The administrator needs to understand the forest, as it is the highest level of the organization hierarchy.
- The administrator needs to understand the organizational unit, as it subdivides and organizes network resources within a domain.
- The administrator needs to understand the replication process, as it copies changes to Active Directory between the domain controllers.

Explanation:

The schema in Active Directory identifies the object classes (the types of objects) in the tree and the attributes (properties) of these objects. This is what the administrator needs to understand to manage the types of objects and their properties in Active Directory.

While understanding the domain controller is important, it does not directly help the administrator understand the types of objects and their properties in the tree.

While understanding the forest is important, it does not directly help the administrator understand the types of objects and their properties in the tree.

While understanding the organizational unit is important, it does not directly help the administrator understand the types of objects and their properties in the tree.

While understanding the replication process is important, it does not directly help the administrator understand the types of objects and their properties in the tree.

q_gpo_computer_01_secp8

You want to ensure that all users in the Development OU have a common set of network communication security settings applied.

Which action should you take?

Answers:

- Create a GPO user policy for the Development OU.
- ***Create a GPO computer policy for the computers in the Development OU.**
- Create a GPO folder policy for the folders containing the files.
- Create a GPO computer policy for the Computers container.

Explanation:

Network communication security settings are configured in the Computer Policies section of a GPO.

Built-in containers (such as the Computers container) and folders cannot be linked to a GPO.

q_gpo_computer_02_secp8

You have several computers running Windows 11. The computers are members of a domain.

For all computers, you want to remove access to administrative tools from the Start menu and hide notifications from the system tray.

What should you do?

Answers:

- ***Use Group Policy**
- Use account restrictions
- Use account policies
- Use file screens

Explanation:

Use Group Policy to control the desktop for groups of users or computers. For example, you can prevent access to specific desktop or Start menu features.

Account policies are specific Group Policy settings that control user passwords. Account restrictions are settings applied in the user account that restrict logon hours or computers.

You use file screens to control the types of files that can be saved within a folder.

q_gpo_linked_01_secp8

A user has complained about not being able to remove a program that is no longer needed on a computer. The Programs and Features page is not available in Control Panel.

You suspect that a policy is enabled that hides this page from the user. But after opening the Local Group Policy Editor, you see that the Hide Programs and Features page is set to Not configured. You know that other users in this domain can access the Programs and Features page.

To determine whether the policy is enabled, where should you look next?

Answers:

- ***GPOs linked to organizational units that contain this user's object.**
- GPOs linked to the domain that contains this user's object.
- The Default Domain Policy GPO.
- The Local Group Policy.

Explanation:

You should look at GPOs linked to organizational units that contain this user's object to see where the Hide Programs and Features page policy might be enabled.

If the policy was enabled in a GPO linked to the domain, it would be applied to all users in the domain.

The next level GPOs are applied from is the level of GPOs linked to organizational units that contain the user's object.

q_gpo_linked_02_secp8

The Hide Programs and Features page setting is configured for a specific user as follows:

Policy	Setting
Local Group Policy	Enabled
Default Domain Policy GPO	Not configured
GPO linked to the user's organizational unit	Disabled

After logging in, the user is able to see the Programs and Features page. Why does this happen?

Answers:

- ***The GPO linked to the user's organizational unit is applied last, so this setting takes precedence.**
- The Default Domain GPO is applied last. It is set to Not configured, so it doesn't change the configuration.
- The Local Group Policy is applied last. It is set to Enabled, which makes the Programs and Features page visible.
- The GPO linked to the user's organizational unit is applied first, so this setting takes precedence over settings that are applied later.

Explanation:

The GPO linked to the user's organizational unit is applied last. With this in mind, the setting that disables the policy to hide the Programs and Features page takes precedence.

In this scenario, Local Group Policy enables the policy to hide the Programs and Features page.

When the Default Domain Policy GPO is applied, this policy is set to Not configured. It doesn't change anything.

When the GPO linked to the user's organizational unit is applied, the setting for this policy is disabled. This reverses the setting in the Local Group Policy and makes the Programs and Features page visible to the user.

The Local Group Policy is applied first. GPOs linked to the user's domain are applied second and take precedence over settings in the Local Group Policy. GPOs linked to the user's organizational unit are applied last and take precedence over any preceding policy settings.

q_gpo_lsdou_secp8

Which of the following is the correct acronym to remember the order in which Group Policy Objects (GPOs) are applied?

Answers:

- OSDL
- ***LSDOU**
- DOLS
- SLOD

Explanation:

LSDOU (Local, Site, Domain, Organizational Unit) is correct. The order of application is Local, Site, Domain, and Organizational Unit.

OSDL (Organizational Unit, Site, Domain, Local) is incorrect. The order of application starts with Local, not Organizational Unit.

DOLS (Domain, Organizational Unit, Local, Site) is incorrect. The order of application starts with Local, not Domain.

SLOD (Site, Local, Organizational Unit, Domain) is incorrect. The order of application starts with Local, not Site.

q_gpo_order_01_secp8

Which statement is true regarding the application of GPO settings?

Answers:

- If a setting is defined in the Local Group Policy on the computer and not defined in the GPO linked to the OU, the setting is not applied.
- If a setting is not defined in the Local Group Policy and is defined in the GPO linked to the OU, the setting is not applied.
- If a setting is defined in the Local Group Policy on the computer and defined differently in the GPO linked to the OU, the Local Group Policy setting is applied.
- ***If a setting is defined in the Local Group Policy on the computer and not defined in the GPO linked to the OU, the setting is applied.**

Explanation:

GPOs are applied in the following order:

1. The Local Group Policy on the computer.
2. GPOs linked to the domain that contains the User or Computer object.
3. GPOs linked to the organizational unit(s) that contain(s) the User or Computer objects (from the highest-level OU to the lowest-level OU).

Individual settings within all GPOs are combined to form the effective Group Policy setting as follows:

- If a setting is defined in one GPO and undefined in another, the defined setting is enforced (regardless of the position of the GPO in the application order).
- If a setting is configured in two GPOs, the setting in the last-applied GPO is used.

q_gpo_order_02_secp8

Group Policy Objects (GPOs) are applied in which of the following orders?

Answers:

- ***Local Group Policy, GPO linked to site, GPO linked to domain, GPO linked to organizational unit (highest to lowest).**
- GPO linked to site, GPO linked to domain, GPO linked to organizational unit (highest to lowest), Local Group Policy.

- Local Group Policy, GPO linked to site, GPO linked to domain, GPO linked to organizational unit (lowest to highest).
- GPO linked to site, GPO linked to domain, GPO linked to organizational unit (lowest to highest), Local Group Policy.

Explanation:

Group Policy Objects (GPOs) are applied in the following order:

- The Local Group Policy on the computer.
- GPOs linked to the site.
- GPOs linked to the domain that contains the User or Computer object.
- GPOs linked to the organizational unit (OU) that contains the User or Computer object (from the highest-level OU to the lowest-level OU).

q_gpo_user_secp8

You manage an Active Directory domain. All users in the domain have a standard set of internet options configured by a GPO linked to the domain, but you want users in the Administrators OU to have a different set of internet options.

What should you do?

Answers:

- Create a GPO computer policy for the Administrators OU.
- ***Create a GPO user policy for the Administrators OU.**
- Create a Local Group Policy on the computers used by members of the Administrators OU.
- Create a GPO user policy for the domain.

Explanation:

Internet options are configured in the User Policies section of a GPO. Linking this policy to the Administrators OU only applies it to users in that OU because GPOs linked to OUs are applied last.

If Local Group Policies are created on the Administrator's computers, the policies are overwritten by the GPO that is linked to the domain, which applies a standard set of internet options to all users in the domain. There is already a GPO user policy linked to the domain.

4.5 Hardening Authentication

As you study this section, answer the following questions:

- What does the minimum password age setting prevent?
- What is a drawback to account lockout for failed password attempts?
- What are the advantages of a self-service password reset management system?

In this section, you will learn to:

- Configure user account restrictions
- Configure account policies and UAC settings
- Use password managers

- Configure account password policies
- Hardening user accounts
- Restrict local accounts
- Secure default accounts
- Enforce user account control
- Configure smart card authentication

The key terms for this section include:

Term	Definition
Multifactor authentication	Using more than one method to authenticate users.
Smart cards	Similar in appearance to credit cards, smart cards have an embedded memory chip that contains encrypted authentication information. These cards are used for authentication.
Microprobing	The process of accessing a smart card's chip surface directly to observe, manipulate, and interfere with the circuit.
Radio frequency identification (RFID)	The wireless, non-contact use of radio frequency waves to transfer data.

This section helps you prepare for the following certification exam objectives:

Exam	Objective

CompTIA Security+ SY0-701	1.2 Summarize fundamental security concepts.
	• Authentication, Authorization, and Accounting (AAA)
	  ○ Authenticating people
	2.4 Given a scenario, analyze indicators of malicious activity.
	• Indicators
	  ○ Account lockout
	  ○ Concurrent session usage
	  ○ Blocked content
	  ○ Impossible travel
	  ○ Resource inaccessibility
	4.5 Given a scenario, modify enterprise capabilities to enhance security.
	• Operating system security
	  ○ Group Policy
	4.6 Given a scenario, implement and maintain identity and access management.
	• Provisioning/de-provisioning user accounts

Exam	Objective

	• Permission assignments and implications
	• Multifactor authentication
	  ○ Implementations
	  ▪ Security keys
	  ○ Factors
	  ▪ Something you have
	• Password concepts
	  ○ Password best practices
	  ▪ Length
	  ▪ Complexity
	  ▪ Reuse
	  ▪ Expiration
	  ▪ Age
	  ○ Password managers
	  ○ Passwordless
	• Privileged access management tools
	  ○ Just-in-time permissions
	  ○ Password vaulting
	  ○ Temporal accounts

4.5.1 Hardening Authentication (Lesson Video)

Transcript:

In this lesson, we're going to talk about hardening authentication. Hardening means strengthening. You want to make sure your authentication methods are strong so you can be confident that the users accessing your network are who they claim to be.

As simple as it may sound, user education is one of the most important parts of authentication hardening. A surprisingly large percentage of security issues within an organization can be tracked back to an employee or another authorized user. While some of these breaches are intentional, many are unintentional; they're a result of a seemingly harmless action.
After all, the strongest doors and the toughest locks become inconsequential if an employee inadvertently opens the door for a potential attacker because they're trying to be helpful.
End user security training should be extensive. For the purpose of authentication hardening, encourage your employees to use password creation methods that they'll remember. Remind them that they shouldn't write down their passwords. Teach them how to recognize social engineering attempts, and remind them not to share their physical or digital access with anyone for any reason.
Next, let's look at passwords more closely. Since passwords are a primary method of authorization, be sure to harden your password policies.
For example, configuring password aging policies causes passwords to be valid for only a specified length of time. After this time has passed, the user will need to change their password.
Enforcing password history prevents the end user from being able to reuse the same password over and over. This can be set for a certain number of times. You might configure your settings so employees can't reuse any of their past five passwords. Or you could set up an indefinite policy so that a user can never use any of the same passwords they've used in the past.
Another way to harden passwords is to enforce password complexity. Doing this prevents users from creating simple passwords like "1234" or "password." When you configure your enforcement policy, you can require capital letters, numbers, or special characters. You can even require that the password be a minimum number of characters long.

You can also allow end users to manage their own passwords without requiring help from the system administrator. This is known as self-service password management. While this can be a convenient option for the user and the administrator, be sure to consider whether it's suitable for your desired level of security.
As we've already discussed, passwords are a common authentication method, and they do provide a layer of security. But just because your network or data is protected by a passwords doesn't mean it's secure.
Whenever possible, you should use multifactor authentication. This means using more than one method to authenticate your users.
End users can authenticate in many ways.
The user could provide something they know, like a password or a PIN.
They could provide something they have, like an ID card or a security token. They could provide something that they are by using their biometric data, such as a palm print, a fingerprint, or a retina scan. Robust authentication processes use two or more of these factors.
Some administrators mistakenly assume that requiring users to supply a username and a password constitutes multifactor authentication. That's incorrect. A username and a password are both items that the end user knows, so they constitute single-factor authentication. If you want to make your authentication process more robust, you can add an additional authentication factor.
For example, you could require a name and password along with a smart card: something that the user knows and something that the user has.
Or you could require a fingerprint scan and a PIN: something that the user is and something that the user knows.
Another way to harden your authentication is to apply restrictions to user accounts. First, you can limit the number of concurrent logins to one per person. This way, if someone forgets to log off of a device, they can't log into a second device without terminating the first connection.
You can also limit when an end user can log in to the system. For example, you may specify that end users can log in between the hours of seven in the morning and six at night. If they try to log in outside of that window, they're blocked.
Another thing you can do is set an account lockout threshold. The account lockout threshold determines the number of failed login attempts that can occur before the user account is locked. Or you could configure a reset lockout counter. The reset lockout counter parameter specifies the amount of time that must pass after a failed login attempt before the failed login counter is reset. This is to slow down password guessing as well as dictionary or brute force attacks.
While we're on the topic of user accounts, let's discuss monitoring and maintenance. Most network administrators are sitting on a pile of data about their users.
There are logs to show when users are signing in, when they're entering incorrect passwords, when they're resetting passwords, where they log in from, and more.
Keeping an eye on activity logs can be kind of dull and time-consuming. So instead of doing it manually, a lot of people use software to do it for them. If unusual or risky behavior is detected, the software will notify you so can act accordingly. This could mean requiring an additional method of authentication, or it could mean locking an account completely.
Maintaining accounts is also important. Some large corporation networks have been breached using outdated or inactive user accounts.
If an employee leaves the organization, that user's account needs to be disabled or deleted. You should also disable inactive accounts. These are commonly associated with contract employees, who only access the network periodically. If the user doesn't need access for a time, disable their account. When the user needs access again, you can re-enable it.
Automatic account expiration is another option where the account is only enabled for a certain amount of time. After that time has passed, the account is automatically disabled. This is especially useful for temporary employees.
You should also make sure that the user accounts have the appropriate level of access. On a Windows network, there are two separate sets of user accounts that you must manage. The first set of accounts resides on the domain controller, and they're managed by the admins.
The second type of accounts are the local user accounts on each individual workstation. These are local accounts. You may not want users to have local administrative access. If they do, they could adjust local file system permissions, install malware, or even create a backdoor user account. Because of this the default administrator account should be the only administrator-level local user accounts on your workstation, and you may want to rename it to obscure it. All other users should be standard users that aren't members of the Administrators group.
You should also disable the local guest user account on each workstation. This account allows someone to authenticate and gain limited access to the system without providing any type of credentials.
Now, let's talk about remote access. The most important thing you can do to harden your remote access is to ensure that it's only enabled for end users who actually need it. Remote-access clients should connect to the internal network through a demilitarize zone, or DMZ. This allows traffic monitoring, which lets you verify that remote access connections are authorized and legitimate. You can also restrict remote access to only certain authorized IP addresses.

In addition, you can limit concurrent logins, such as only one per user. Every time a remote user connects, their last login date and time should be displayed. This allows the end user to see if somebody else has been using their connection to gain access to the network.
Lastly, you should audit remote logins. Check to see if remote connections are made at suspicious times or from suspicious IP addresses, and check for a spike in the number of failed logins. All these events indicate that some type of attack is probably being conducted.
And that's it for this lesson. In this video, we discussed hardening authentication through user education, stronger passwords, multifactor authentication, account restrictions, account monitoring, account maintenance, and limited remote access.

4.5.2 Configure User Account Restrictions (Demo Video)

Transcript:

In this demonstration, we'll look at hardening a Windows workstation by configuring user account restrictions. By setting these restrictions in a domain, they will always be applied, even if the user logs in from a different system, or if a different user logs into system.

Let's begin by opening Active Directory Users and Computers. Let's drill down into the Employees OU so we can see our users.
First, we need to do several things to harden these accounts. Let's choose the temporary employee, Daniel Jackson.
There are several things we can do to harden his account, specifically because he's a temporary employee.
This user works Monday through Friday from 8:00 in the morning until 5:00 at night. We need to restrict the user's logon hours and days to the times he is working. Also, because the user is a temporary employee, we should configure the account to expire automatically when the employment term expires.
We want to disable the account automatically in case we forget to manually disable it.
First, let's go into Account settings > Logon Hours. Everything that is highlighted in blue is a permitted logon block or hour.
You can see the days here, Sunday through Saturday, and anything highlighted in white will be logon denied. In this case, we want to limit logon to Monday through Friday, 8:00 a.m. through 5:00 p.m. If we select Saturday and select Logon Denied, it denies logon for the whole day. It whites it all out. We'll select Sunday, as well.
We'll select all the days from midnight 8:00 a.m and disable those. Then we'll go from here to 5:00 p.m to midnight and disable those hours. Now he only has login permitted from 8 a.m. to 5 p.m. Monday through Friday. We click OK, and that applies the restriction.
We also need to set the account expiration. You can see it's set to Never. We want to change this. Let's say this account will expire at the end of the year. We'll click December 31. We'll click Apply. Click OK.
Now Daniel Jackson's account will automatically deny him access unless he's logging in Monday through Friday, 8:00 a.m. to 5:00 p.m. The account will be disabled automatically on December 31, at the end of the day.
Also, in this OU, we have an employee who's on extended leave.
Samantha Carter has been out on maternity leave, so her account is disabled. We did not delete her account because we are expecting her to come back to work, and we don't want to have to recreate all her permissions when she returns.
Samantha is returning tomorrow, so let's re-enable her account.
To do this, come up here and right-click the account, and enable account. Notice that the little black arrow on the user icon disappeared – that means the account is now enabled again.
The last thing we want to do in this demonstration is restrict a user to a particular computer on the network. The user will be allowed to log on only from that system. Let's say the user, Samantha Carter, is allowed to log in only on the lab computer.
Let's go to Properties. We'll go to Account and click Log On To... As you can see here, the user can currently log in to all computers on the domain. We don't want that because the user should only be in the lab.
We'll set it manually. Here, you type in the computer name after selecting the following computers. You type in the computer's net bios, domain name, or DNS name.
Let's type in 'LabComputer' and click Add. Notice this is the only computer listed now for the user. So, this is the only computer the user can log in to.
You can add more than one computer. Let's click OK. Now this user can log in only to that lab computer.

That's it for this demonstration. In this demonstration, we showed you how to configure user account restrictions. We first looked at how to restrict login times for a given user account.
We disabled and enabled user accounts. We set an expiration date for an account. Then we ended the demonstration by configuring a user account to use a specific computer in the network.

4.5.3 Configure Account Policies and UAC Settings (Demo Video)

Transcript:

In this demonstration, we'll show you actions you can take to harden Windows authentication. First, we'll configure account policies that will be applied to all the users in the domain.

Then, we'll enforce UAC settings. An easy way to enforce UAC settings is to make the configuration changes to a GPO in the domain. When you use a GPO, settings are automatically enforced on each workstation whenever a user logs in to the domain.
Using Group Policy, you make the changes once, instead of having to do it manually on each workstation.
Let's go to Tools > Group Policy Management and right-click Default Domain Policy. Click Edit. That opens the Group Policy Management Editor. Then, let's go to Computer Configuration > Policies > Window Settings > Security Settings > Account Policies > Password Policy.
Here, you see the password policies that are available.
First, let's change the minimum password length from seven characters to a more secure 10 characters.
The value you choose for many of these settings depends on your environment, the organization, and how you want to balance security with ease of use for the users.
If you set the password policy too high, it might be difficult for users to manage. We'll set the password length at 10 because that's a reasonable number of characters for a password.
Now, let's go to Enforce Password History. The value is set to 24. This means the system keeps a 24-password history. That prevents users from repeating recent passwords.
This policy makes sure that users can't reuse a password until they have made 24 different password changes. Click OK. That's fine where it's set.
Let's change our maximum password age. We're going to change that to 30 days.
A minimum password age of one day means the user could change the password every day. Some users might try changing the password every day, so they get back to an old password after 24 days of passwords changes. We don't want to allow that.
Let's change the minimum password age to 10 days. That means users have to keep a password for 10 days.
Now, let's look at password complexity requirements. These are basic complexity requirements that Windows has defined.
In most cases when you click the Explain tab, it'll provide more information about the policy setting. Here you can see all the password requirements that Windows has set. So, we'll click OK.
After configuring password policies, let's configure the account lockout policies. If we go here, the first one we'll look at is the account lockout threshold.
You can see that it's currently set to 0 invalid logon attempts. Let's double-click it. Zero invalid logon attempts mean it's not enabled. It's defined, but a policy set at zero is, by definition, not enabled.
Let's change this to 3. That means, after three invalid password entries, the account will lock. Click OK.
If you look, this automatically sets the other two values for the account lockout policy to 10 minutes each. Let's go into these.
The Account Lockout duration determines the length of time before a locked account will automatically be unlocked. The Reset Account Lockout Counter determines how long an invalid password attempt will be counted toward the Account Lockout Threshold.
10 minutes is fine for both of these settings, so I'm going to leave them as-is.
The next thing we'll look at is the User Account Control. If we go to Local Policies > Security Options, we can look at the UAC settings.
A word of caution – configuring the UAC incorrectly can cause some real problems. It can generate excessive elevation prompts, it can cause applications not to install correctly, and be a source of frustration for your users and your help desk. For this video, we're going to go through each of these settings and configure the group policy according to how the UAC behaves by default.

It's always a good idea to put new settings into a new group policy object. So, let's close this and go back to the Group Policy Management. We'll go into the Group Policy Objects folder and right click, then select New to create a new GPO. We'll call this UAC Settings.
We'll edit this GPO and go to Computer Configuration, Policies, Windows Settings, Security Settings, Local Policies, Security Settings, and scroll down to the bottom.
You can read more about what each of these settings do in the description. Here is how we are going to configure them for this video.
Admin Approval Mode for the Built-in Administrator account will be enabled.
Allow UIAccess applications to prompt for elevation without using the Secure Desktop will be disabled.
Behavior of the elevation prompt for administrators in Admin Approval Mode will be set to "Prompt for consent for non-Windows binaries".
Behavior of the elevation prompt for standard users will be set to "Prompt for credentials on the secure desktop".
Detect application installations and prompt for elevation will be enabled.
Only elevate executables that are signed and validated will be disabled.
Only elevate UIAccess applications that are installed in secure locations will be enabled.
Run all administrators in Admin Approval Mode will be enabled.
Switch to the secure desktop when prompting for elevation will be enabled.
And last, virtualize file and registry write failures to per-user locations will be enabled.
Now that I have the GPO configured the way I want, I just need to apply it to an OU, and all the computers beneath that OU will inherit the settings from it.
That concludes this demo. In this demonstration, we hardened Windows authentication.

4.5.4 Use Password Managers (Demo Video)

Transcript:

With the large number of passwords you may accumulate from websites, computer logins, or even network equipment, you may consider using a password manager to store your passwords securely. Most password managers offer a way to configure two-factor authentication, so in the event a hacker obtains your password for the password manager, they'd be stopped by the two-factor authentication process used to log in to the password manager.

Today, we're going to look at a product called Bitwarden. This is a very popular password manager that offers excellent protection for your passwords. Best of all, the starting plan for this is free. There are some options, as you can see here, that offer better protection if you decide to pay. Some of these options include Advanced 2FA, which is the same as two-factor authentication. If you have a business, you can use a paid business option to store your business passwords.
We've already created our Bitwarden account; however, when you create your account, two-factor authentication (2FA) isn't set up yet. To set this up, we must go to our account options and select Account settings. On the Security tab, there will be an option for Two-step login. The paid options allow the use of Yubikey, Duo, or WebAuthn. For this account, we'll set up an authenticator app and use Authy. It will first prompt for the master password just to make sure you want to do this.
This next screen is important. From here, you'd download your authenticator app on your phone. Two examples are Authy and Google Authenticator. Although I can't show the app part, once installed, you can bring up the app, add an account, and then use your phone's camera to scan the QR code to simply add Bitwarden to Authy. Once added, use the latest six-digit code from Authy to finish this setup.
Now that we have 2FA set up let's test it out. If we Log out of our account and then re-enter our email address and password, you'll see that it will now prompt for a 2FA code instead of just logging you in. After we input our six-digit code, we're successfully logged in.
Our authentication is configured properly, so let's add some passwords. All we have to do is click New Item. We can define what this item is, like a Login, Card, Identity, or a Secure note. For now, let's stick with Login. Next, we need to give it a name, configure a username, and input the password. Keep in mind this will save the password for whatever login you've already configured, say from Outlook, Yahoo, or even your favorite forum site.
In order for a browser extension to pick up the password, you must set a URL. We'll see why in the next step. If, by chance, you wish to write a note about this password, it gives you that option. Let's Save our password.
This next part makes it super easy to log in to websites. Most password managers have a browser extension, so let's add that. Going to the three dots and selecting Extensions allows us to find the one we're looking for. After typing

Bitwarden, this is the one we want. Extensions don't always show up on the toolbar, so let's change that setting. Going back to our Extension settings, we can choose to make Bitwarden show in the toolbar. This makes it a lot easier to access passwords. When the extension is set up, we'll be required to re-login with our username, password, and code from our authenticator app. Regardless of whether it's logging into Bitwarden on a website, extension, or even a phone app, it should be the same process.
The main thing we want to see is if the username and password get populated in the fields presented on a website, so let's test this. Two ways we can get to the site are to manually type it in or use the arrow button to launch the URL from the password. Either way, you'll get to the same place. Once you click Sign in, you'll be prompted for your email. You can see that when we go up to our Bitwarden extension, we have one available login. When clicked, it will populate the fields on the screen. It will also do the same for the password—granted, this isn't a real login; however, you get the idea of how it can auto-populate a username and password without typing it in each time.
Let's go back to Bitwarden to show some other features. Say you'd like to put a secure note in; what we could do is add a New Item. In this case, we're going to select a Secure note. Say this is my combination lock for my shed, and I don't want to forget this combination. We could write a note for this and then Save it. Now, you can see how useful this password manager can be in securing all your information.
That's it for this demo. In this demo, we showed you how to set up and configure a password manager.

4.5.5 Configure Account Password Policies (Simulation)

Scenario

You have been asked to perform administrative tasks for a computer that is not a member of a domain. To increase security and prevent unauthorized access to the computer, you need to configure specific password and account lockout policies.

In this lab, your task is to use the Local Security Policy to configure the following password and account lockout policies:

- Configure password settings so that the user must:
    - Cycle through ten passwords before reusing an old one.
    - Change the password every 90 days.
    - Keep the password for at least 14 days.
    - Create a password at least eight characters long.
    - Create a password that meets complexity requirements, such as using uppercase letters, lowercase letters, numbers, or symbols.
- Configure the account lockout policy to:
    - Lock out any user who enters five incorrect passwords.
    - Unlock an account automatically after 60 minutes.
    - Configure the number of minutes that must elapse after a failed logon attempt to 10 minutes.
-

Explanation

In this lab, your task is to edit the Local Security Policy and configure settings as follows:

Policy Location	Policy	Setting
Account Policies/Password Policy	**Enforce password history**	**10**
	Maximum password age	**90**

	Minimum password age	**14**
	Minimum password length	**8**
	Passwords must meet complexity requirements	**Enabled**
Account Policies/Account Lockout Policy	**Account lockout threshold**	**5**
	Account lockout duration	**60**
	Reset account lockout counter after	**10**

Complete this lab as follows:

1. Using Windows Administrative Tools, access the Local Security Policy.
   a. Select **Start** .
   b. Locate and expand **Windows Administrative Tools** .
   c. Select **Local Security Policy** .
   d. Maximize the window for better viewing.
2. Configure the password policies.
   a. From the left pane, expand and select **Account Policies** > **Password Policy** .
   b. From the center pane, expand the **Policy** column.
   c. Double-click the ***policy*** to be configured.
   d. Configure the ***policy settings*** .
   e. Select **OK** .
   f. Repeat steps 2c-2e to configure the additional password policies.
3. Configure the account lockout policies.
   a. From the left pane, select **Account Lockout Policy** .
   b. From the center pane, expand the **Policy** column.
   c. Double-click the ***policy*** to be configured.
   d. Configure the ***policy settings*** (if needed, answer any prompts shown).
   e. Select **OK** .
   f. Repeat steps 3c-3e to configure the additional lockout policies.

4.5.6 Hardening User Accounts (Demo Video)

Transcript:

In this demonstration, we'll look at things you can do to harden Windows workstation authentication within your network. First, we'll look at restricting local accounts.

We want to ensure that only authorized users have administrative rights to the local Windows operating system. If a workstation is joined to a domain, then we typically use a domain user account to authenticate.
However, we sometimes forget that there are still local user accounts on each individual Windows workstation. One or more of them may have administrative access to the local systems; this presents a security issue.
A better option is to configure these settings in a GPO in the domain. This will allow you to make these configuration settings once and have them automatically enforced on every workstation.

To begin, we'll go to Tools > Group Policy Management > Group Policy Objects, and create a new GPO. We'll call this "Restrict Admin Group Membership". Go to Edit.
As you know, when you install a Windows workstation, several user accounts are created by default. You define administrator, guest, and user accounts during the installation process.
We want to harden authentication by renaming the default administrator account to something that makes it less obvious that the account is an administrator.
We also want to disable the guest account. It provides a degree of access to the system without a password. We also want to look for any local user account that has the Password never expires option enabled.
We'll do this with our group policy. We'll navigate to Computer Configuration > Policies > Windows Settings > Security Settings > Local Policies > Security Options. We're going to enable the option to rename the Administrator account, we'll rename the administrator account to 'Elvis'. And we'll set the Guest Account Status option so this GPO will disable the Guest account.
Next, we need to make sure that administrative rights are only given to the groups we define. We're going to use a group policy feature called Restricted Groups. Use caution when adding entries in Restricted Groups. We're going to create an entry that defines who is in the Administrators group. When you define a group membership with a Restricted Group setting, it will evict any member of the group that isn't defined by your group policy. This is a highly effective way to make sure admin rights do not get assigned outside of group policy. However, there is a risk you will evict an account that needs admin rights. If that happens, you just need to be prepared for it, and define that account with the group policy setting we're about to show you.
We'll navigate to Computer Configuration > Policies > Security Settings > Restricted Groups. We'll right click and create a new entry for "BUILTIN\Administrators".
We also want to add our domain admins to this group.
And we'll add one more entry for the "Elvis" account – that we renamed our Administrator account.
Let's click OK. Now we can see this is created right here. Next, we want to secure the default accounts on each workstation.
All user accounts should have their passwords changed on a regular schedule.
We also want to look for any user accounts that have never been used. The default for creating a new local user account on a Windows workstation should have the option User must change password at next logon enabled.
Therefore, we're going to assume that any user account that has that option marked has never been used because the user has never logged in. We want to get rid of all accounts that have never been used.
To do this, we'll switch over to the Windows 11 workstation. We'll right-click in the window and go to Computer Management.
Now we're going to go to Local Users and Groups > Users. This shows the users currently on the system.
The next thing we want to look at are accounts that have never been logged in to. If we double-click this account right here, for Mr. Hank Hill, you can see the option to require password change at login is not checked. That's good.
This means that this user has logged in before. If we look at this one, now you can see this says User must change password at next login.
This means this user has never logged in, which means this account is just sitting here and, possibly, is an account that's not needed. Most likely, that's the case. We'll delete this account because we probably don't need it.
The other thing you want to look for is the Password never expires checkmark. We'll check our TestOut account.
We'll leave this in for our purposes. But normally, you don't want a normal user to have a password that never expires.
If you do have this option enabled on your Windows workstations, you probably want to uncheck it and require that the user has to change the password, just like normal accounts on the domain. For now, we're going to click OK.
That's it for this demonstration. In this demo, we hardened Windows authentication for Windows workstations in a network.

4.5.7 Restrict Local Accounts (Simulation)

Scenario

You are the IT security administrator for a small corporate network. You are working to increase the authentication security of the domain. You need to ensure that only authorized users have administrative rights to all local machines. Local users and groups can be controlled through a GPO linked to the domain.

In this lab, your task is to edit the Default Domain Policy and configure the Local Users and Groups policy settings as follows:

- Create a policy to update the built-in Administrator local group.
- Delete all member users.
- Delete all member groups.
- Add **BUILTIN\Administrator** to the group.
- Add **%DOMAINNAME%\Domain Admins** to the group.

The policy you create should remove all members of the built-in Administrators group and then add only the members specified. Use **BUILTIN\Administrator** and **%DOMAINNAME%\Domain Admins** in the policy to indicate which accounts to add.

Explanation

Complete this lab as follows:

1. Access the **CorpNet.local** domain under Group Policy Management.
    a. From Server Manager, select **Tools** > **Group Policy Management** .
    b. Maximize the windows for better viewing.
    c. Expand **Forest: CorpNet.local** > **Domains** > **CorpNet.local** .
2. Create a policy to update the built-in Administrator local group.

a. Right-click **Default Domain Policy** and select **Edit** .
    b. Maximize the windows for better viewing.
    c. Under Computer Configuration, expand **Preferences** > **Control Panel Settings** .
    d. Right-click **Local Users and Groups** and select **New** > **Local Group** .
    e. Using the *Group name* drop-down, select **Administrators (built-in)** .
    f. Select **Delete all member users** to remove all member users.
    g. Select **Delete all member groups** to remove all member groups.
    h. Select **Add** .
    i. In the *Name* field, enter **BUILTIN\Administrator** and then select **OK** .
    j. Select **Add** .
    k. In the *Name* field, enter **%DOMAINNAME%\Domain Admins** and then select **OK** .
    l. Select **OK** to save the policy.

4.5.8 Secure Default Accounts (Simulation)

Scenario

You work as the IT security administrator for a small corporate network. You are improving office computers' security by renaming and disabling default accounts.

In this lab, your task is to perform the following on the Office1 computer:

- Rename the Administrator account, **Yoda** .
- Disable the Guest account.
- Verify that *Password never expires* is not selected for any local users. This forces them to change their passwords regularly.
- Delete any user accounts with *User must change password at next logon* selected. This indicates that a user has never logged in.

Explanation

Complete this lab as follows:

1. Access the computer's Computer Management tool.
    a. Right-click **Start** and select **Computer Management** .
    b. Under System Tools, expand **Local Users and Groups** .
    c. Select **Users** .
2. Rename the Administrator account.
    a. From the center pane, right-click **Administrator** and select **Rename** .
    b. Enter **Yoda** and press **Enter** .
3. Disable the Guest account.
    a. Right-click **Guest** and select **Properties** .
    b. Select **Account is disabled** and select **OK** .
4. Remove Password never expires option if it is selected.
    a. Right-click a ***user*** and select **Properties** .
    b. Deselect **Password never expires** (if selected) and then select **OK** .
    c. Make a note of any user who has *User must change password at next logon* .
    d. Repeat steps 4a-4c for each user.
5. Delete any unused accounts.
    a. Right-click the ***user*** that has **User must change password at next logon** selected and select **Delete** .
    b. Select **Yes** to confirm the deletion of the account.

4.5.9 Enforce User Account Control (Simulation)

Scenario

You are the IT administrator for a small corporate network. The company has a single Active Directory domain named CorpNet.local. You need to increase the domain's authentication security. You need to make sure that User Account Control (UAC) settings are consistent throughout the domain and in accordance with industry recommendations.

In this lab, your task is to configure the following UAC settings in the Default Domain Policy on CorpDC as follows:

User Account Control	Setting
Admin Approval mode for the built-in Administrator account	**Enabled**
Allow UIAccess applications to prompt for elevation without using the secure desktop	**Disabled**
Behavior of the elevation prompt for administrators in Admin Approval mode	**Prompt for credentials**
Behavior of the elevation prompt for standard users	**Automatically deny elevation requests**
Detect application installations and prompt for elevation	**Enabled**
Only elevate UIAccess applications that are installed in secure locations	**Enabled**
Only elevate executables that are signed and validated	**Disabled**
Run all administrators in Admin Approval mode	**Enabled**

Switch to the secure desktop when prompting for elevation	**Enabled**
Virtualize file and registry write failures to per-user locations	**Enabled**

User Account Control policies are set in a GPO linked to the domain. In this scenario, edit the Default Domain Policy and configure settings in the following path:
Computer Configuration > **Policies** > **Windows Settings** > **Security Settings** > **Local Policies** > **Security Options** .

Explanation

While completing this lab, use the following information when configuring the UAC settings.

User Account Control	Setting
Admin Approval mode for the built-in Administrator account	**Enabled**
Allow UIAccess applications to prompt for elevation without using the secure desktop	**Disabled**
Behavior of the elevation prompt for administrators in Admin Approval mode	**Prompt for credentials**
Behavior of the elevation prompt for standard users	**Automatically deny elevation requests**
Detect application installations and prompt for elevation	**Enabled**
Only elevate executables that are signed and validated	**Disabled**
Only elevate UIAccess applications that are installed in secure locations	**Enabled**
Run all administrators in Admin Approval mode	**Enabled**
Switch to the secure desktop when prompting for elevation	**Enabled**
Virtualize file and registry write failures to per-user locations	**Enabled**

Complete this lab as follows:

1. On CorpDC, access the **CorpNet.local** domain for Group Policy Management.
    a. From Server Manager, select **Tools** > **Group Policy Management** .
    b. Maximize the window for easy viewing.
    c. Expand **Forest: CorpNet.local** > **Domains** > **CorpNet.local** .
2. Configure the UAC settings.
    a. Right-click **Default Domain Policy** and select **Edit** .
    b. Maximize the window for better viewing.
    c. Under Computer Configuration, expand and select **Policies** > **Windows Settings** > **Security Settings** > **Local Policies** > **Security Options** .
    d. From the right pane, double-click the ***policy*** you want to edit.

e. Select **Define this policy setting** .
f. Select **Enable** or **Disable** as necessary.
g. Edit the ***value*** for the policy as needed, and then select **OK** .
h. Repeat steps 2d–2g for each policy setting.

4.5.10 Hardening Authentication Facts

This lesson covers the following topics:

- Hardening authentication methods
- Hardening authentication best practices

Hardening Authentication Methods

Hardening means to strengthen. You want to make sure your authentication methods are strong so that you can be confident that users accessing your network are who they say they are.

The following table provides various methods for strengthening your authentication.

Method	Description
Password Policies	Account policies help you control the composition and use of passwords. Password policies include: • Enforce password history - This determines the number of unique new passwords that have to be used before an old password can be reused. This helps to prevent users from reusing any recent passwords. • Maximum password age - This requires users to change their password after a given number of days. • Minimum password age - This determines the number of days that a password must be used before the user can change it. This prevents users from reverting back to their original password immediately after they have changed it. • Minimum password length - This identifies the minimum number of characters in a password. • Password must meet complexity requirements - A complex password prevents using passwords that are easy to guess or crack. Complex passwords must meet the following minimum requirements: ○ Cannot contain the user's account name or parts of the user's full name that exceed two consecutive characters ○ Must be at least six characters in length ○ Must contain characters from three of the following four categories: ▪ English uppercase characters (A through Z) ▪ English lowercase characters (a through z) ▪ Base-10 digits (0 through 9) ▪ Non-alphabetic characters (for example, !, $, #, or %) Complexity requirements are enforced when passwords are changed or created.

Multifactor Authentication	When possible, multifactor authentication should be used. This means using more than one method to authenticate your users. End users can be authenticated using three types of factors: • Something you know • Something you have • Something you are Robust authentication processes use two or more of these factors.
Account Restrictions	Account restrictions place restrictions on the use of a user account for login. For example, you can: • Prohibit multiple concurrent logins • Allow logins only during certain days and hours • Allow logins only from specific computers • Create expiration dates for user accounts for temporary users to prevent them from being used past a certain date
Account Monitoring	Account monitoring can help you detect unusual or risky behavior. You should monitor for the following: • Login activity. • Suspicious logins for the user (spikes, logins at unusual time of day, and/or frequent or failed logins). • Remote-access traffic.
Account Maintenance	The following list provides best practices for account maintenance: • Delete an employee's account when the employee leaves the organization. • Disable inactive accounts. • Use automatic account expiration when applicable. • Restrict remote access only to authorized clients (filtering by IP address).
Limit Remote Access	The following precautions should be taken when administering remote access: • Allow remote access to the network only for those users who need it to perform their duties (not standard for all users). • Do not allow remote access clients to connect directly to the internal network. Allow remote access clients to connect to a DMZ and then monitor the traffic. • Restrict remote access only to authorized clients . You can filter by IP address.
Account Lockout Policies	Account lockout disables a user account after a specified number of incorrect login attempts. Account lockout policies include:

	• Account lockout duration - Specifies the number of minutes a locked-out account remains locked out before automatically becoming unlocked. When set to 0, an administrator must unlock the account. • Account lockout threshold - Specifies the number of failed logon attempts that causes a user account to be locked out. • Reset account lockout counter after - Specifies the number of minutes that must elapse after a failed logon attempt before the failed logon attempt counter is reset to 0 bad logon attempts. For example, if this value is set to 60 minutes and the account lockout threshold is set to 5, the user can enter up to four incorrect passwords within one hour without the account being locked. Account lockout can be used to prevent attackers from guessing passwords, but it can also be used maliciously to lock an account and prevent a valid user from logging in.

Hardening Authentication Best Practices

When controlling user account and password security, be aware of the following:

- For large environments, implement a password management system with a self-service password reset management system. This allows a user to change his or her own password and ensures that only he or she knows it. In a system where administrators hand out passwords that users cannot change, passwords lack security. In this type of arrangement, no matter how complex the password is, more than one person knows what it is. This can affect the security of the system.
- Implement account auditing to track incorrect login attempts. Small numbers of incorrect logon attempts occur naturally as users mistype or forget passwords. Large numbers of incorrect login attempts could identify a potential hacker trying to guess passwords.
- Scan systems to identify unused user accounts or accounts with blank passwords.
- When implementing account lockout and account policies on Microsoft systems:
    - The Local Security Policy controls policies for user accounts that are defined on a local system.
    - Policy settings in Group Policy are linked to the domain control settings for all user accounts in the domain. Settings defined at other levels in Group Policy do not affect password or account lockout settings.
- Disable and/or remove unnecessary accounts installed on the operating system by default, or disable specific user accounts that are no longer needed.
- Prohibit the use of generic user accounts. Generic accounts, such as guest or administrator accounts in Windows, should be disabled.
- Prohibit the use of shared user accounts.
  Shared accounts:
    - Increase the likelihood of the account being compromised. Because the account is shared, users tend to take security for the account less seriously. For example, one organization found that the passwords for shared user accounts proliferated to the point where hundreds of current and former employees knew them.
    - Make password management more difficult. Because password changes must be communicated to multiple users, many system administrators avoid making any password changes at all. If the password is well known, employees (including former employees that no longer need access to the account) may still know the password.
    - Reduce responsibility for the account. Because users view the account as communal, users may do things with the account that they would not do with their personal account.
    - Destroy audit trails for the account. Because multiple users are associated with the account, it can be difficult to identify who is actually responsible for actions performed with the account.

- Make it difficult to monitor the account for unusual activity. Because multiple users are associated with the account, it is much more difficult to define behaviors that are normal and behaviors that are abnormal. This is problematic because identifying abnormal account activity is key to detecting attacks on your systems.

4.5.11 Configure Smart Card Authentication (Demo Video)

Transcript:

In this demonstration, we'll look at using Group Policy to enforce smart card authentication on computers in a domain. We'll do this by making it so all computers in the research and development department and all administrators need to have a smart card in order to log on.

So, first, let's start by working on the first group, the research and development employees. So, in Server Manager, we're going to go to Tools. We're going to open Group Policy Management. We'll go here, to our Research and Development OU. You can see, in this domain, that we already have that OU created.
Notice that we've already created a Group Policy object and linked it to the Research and Development department OU. So, we'll right-click this Group Policy object and click Edit to open Group Policy Management Editor.
Now, we need to enable two different policies in this Group Policy object to enforce smart card authentication. First, we need to locate a policy named Interactive logon that requires a smart card and enable it. After that, we need to set the interactive log on smart card removal behavior to force log off.
So, let us enable the first policy. Because these are computer policies and not user policies, we'll expand Policies under Computer Configuration. We'll navigate to Windows > Security Settings > Local Policies and then Security Options. Now we need to scroll down to Interactive logon session and locate the policy titled Require Windows Hello for Business or smart card. Keep in mind that because we are editing settings within the Computer Configuration portion of this GPO, the settings will be applied to computers and not to users. If a user in this OU logs onto a computer outside the OU where this policy is applied, they'll not need a smart card.
We're going to double-click the policy. First, we'll define this policy and then enable it. If we click OK, we have just specified that any machines within Research and Development will require a smart card to log in.
The next policy we need to look at is called Interactive logon: Smart card removal behavior. As you can see, it is the one right below it. Double-click that policy. Now, we define this policy. We select Force Logoff. We'll click OK.
We can close the Group Policy Management Editor at this point. Now, we can look and see if the GPO is enforced or not. If you look right here, you can see that the GPO Enforced is labeled as No, which means that the GPO is currently not enforced.
There is no little lock icon, meaning the policy isn't enforced. So, when a GPO is enforced, it means that the settings we specify here in the GPO can't be overruled by another GPO that may be linked to a lower organizational unit within the OU, where the GPO is linked.
So, if we don't enforce it, another GPO, like the one in this sub-OU, could potentially override the settings we defined in our RND GPO right here. Since we don't want that to happen, we want this GPO to be enforced.
We'll right-click on the GPO and select Enforced. Now, the GPO is enforced. Now, no matter what we do at lower layers within this OU, this GPO will always be enforced. The next time someone logs into a computer within Research and Development, they'll have to have a smart card to do so.
If they have their smart card, then they can use it to authenticate. And if they remove the smart card, they'll automatically be forced to log off. So, let's do the same thing for our administrative users. We'll do this through Active Directory Computers and Users. Let's go ahead and close the Group Policy Management window. We'll go to Tools and then Active Directory Users and Computers.
Now we'll go to our Admins OU I've created. Within the Admins OU are all of our administrative users in the domain. We want these users to be forced to use smart card authentication. So, let's click the first user, and we'll highlight both users. If we right-click both of these at the same time, as they are both highlighted, it will open the Properties for all of the users at once.
If you have four or five users, it can be really helpful, so you don't have to go through and do it to each account. Now, we'll click on the Account tab. You can see, down here, that we're going to scroll down to Smart card is required for interactive logon. Select that.

If we click OK, that change is made for all the admin users here. There's one more account we need to do this for, and that is the Default Administrator User account created when Active Directory was initially installed. We'll go into our Users OU.
You can see the default account here. We'll right-click, go to Properties, go to Account, and we can scroll down until Smart card is required for interactive login. We're going to hit OK. Now, when any of these admin users try to authenticate to their local machine using a domain account, they'll be required to have a smart card for authentication.
That's it for this demonstration. In this demo, we talked about enforcing the use of a smart card for authentication to the local computer systems in our domain. We first edited the Group Policy associated with an OU in the domain and required smart card authentication for any computers in that OU. We made it so that if they remove their smart card, they'll be forced to log off immediately. We then required a smart card for user authentication for all administrative users in the domain.

4.5.12 Configure Smart Card Authentication (Simulation)

Scenario

You work as the IT administrator for a growing corporate network. The Research and Development Department is working on product enhancements. Last year, some secret product plans were compromised. As a result, the company decided to implement smart cards for logging on to every computer in the Research and Development Department. No user should be able to log onto the workstation without using a smart card.

In this lab, your task is to perform the following on CorpDC:

- Enforce the existing Research-DevGPO linked to the Research-Dev OU.
- Edit the Research-DevGPO and configure the following local security setting policies located in the Computer Configuration section:

Policy	Setting
Interactive logon: Require smart card	**Enabled**
Interactive logon: Smart card removal behavior	**Force logoff**

Certificate auto-enrollment has already been enabled for the domain.

Explanation

While completing this lab, use the following information to configure the following Security Options policies:

Policy	Setting
Interactive logon: Require smart card	**Enabled**
Interactive logon: Smart card removal behavior	**Force logoff**

Complete this lab as follows:

1. Access the **CorpDC** server.
    a. In Hyper-V Manager, select **CORPSERVER** .
    b. Double-click **CorpDC** .
2. Enforce the existing Research-DevGPO.
    a. From Server Manager, select **Tools** > **Group Policy Management** .
    b. Maximize the window for better viewing.
    c. From the left pane, expand **Forest: CorpNet.local** > **Domains** > **CorpNet.local** > **Group Policy Objects** .
    d. From the left pane, select the **Research-DevGPO** .
    e. From the Scope tab, under Links, right-click **Research-Dev** and then select **Enforced** .
3. Edit Research-DevGPO policies.
    a. From the left pane, right-click **Research-DevGPO** and then select **Edit** .
    b. Maximize the window for better viewing.
    c. Under Computer Configuration, expand **Policies** > **Windows Settings** > **Security Settings** > **Local Policies** .
    d. Select **Security Options** .
    e. From the right pane, double-click the ***policy*** .
    f. Select **Define this policy setting** .
    g. Select additional ***parameters*** to configure the policy setting.
    h. Select **OK** .
    i. Repeat steps 3e-3h to configure the additional policy setting.

4.5.13 Smart Card Authentication Facts

This lesson covers the following topics:

- Smart cards
- Smart card benefits and weaknesses

Smart Cards

Smart cards are plastic cards similar to credit cards that have an embedded memory chip that contains encrypted authentication information. Be aware that smart cards:

- Use public key infrastructure (PKI) technology to store digital signatures, cryptography keys, and identification codes.
- Can authenticate a user when used in conjunction with a smart card reader connected to a computer system.
- Typically have RAM, ROM, programmable ROM, and a microprocessor integrated within the card itself.
- Have their own processor, allowing the card to perform its own cryptographic functions.
- Use a serial interface to connect to the card reader.
- Are powered externally by the smart card reader.
- Are generally considered to be tamper-proof.
- Can be divided into two categories:
    - Contact smart cards: these cards use a gold-plated contact pad that must physically touch the contact pad on a smart card reader.
    - Contactless smart cards: these cards do not require physical contact with the reader device. Instead, these cards use Radio Frequency Identification (RFID) technology to communicate with the smart card reader. An antenna is wound around the edge of the card and activated when the card is within proximity of the card reader.

Smart Card Benefits and Weaknesses

Key benefits of smart cards include the following:

- They provide tamper-resistant storage for a user's private key and other personally identifying information (PII).
- They isolate security-related operations from the rest of the system.
- They allow security credentials to be portable.

Smart cards are subject to the following weaknesses:

- Microprobing - this is the process of accessing the chip surface directly to observe, manipulate, and interfere with the circuit.
- Software attacks - these exploit vulnerabilities in the card's protocols or encryption methods.
- Eavesdropping - this captures transmission data produced by the card as it is used.
- Fault generation - this deliberately induces malfunctions in the card.

4.5.14 Practice Questions (Section Quiz)

q_harden_auth_complex_01_secp8

You want to make sure that all users have passwords over eight characters in length and that passwords must be changed every 30 days.

What should you do?

Answers:

- ***Configure account policies in Group Policy.**
- Configure account lockout policies in Group Policy.
- Configure expiration settings in user accounts.
- Configure day/time settings in user accounts.

Explanation:

Configure account (password) policies in Group Policy to enforce rules about the composition of passwords, such as minimum length, complexity, and history requirements.

Use account expiration in a user account to disable an account after a specific day.

Use day/time restrictions to prevent login during certain days or hours.

Account lockout disables a user account after a specified number of incorrect login attempts.

q_harden_auth_complex_02_secp8

You are configuring the Local Security Policy of a Windows system. You want to require users to create passwords that are at least ten characters in length. You also want to prevent login after three unsuccessful login attempts.

Which policies should you configure? (Select two.)

Answers:

- ***Minimum password length**
- Enforce password history
- Account lockout duration
- ***Account lockout threshold**
- Maximum password age
- Password must meet complexity requirements

Explanation:

Set the *Minimum password length* policy to require a password equal to or longer than the specified length. Set the *Account lockout threshold* policy to lock an account after the specified number of incorrect login attempts.

The following lists explains the incorrect policy choices for this scenario:

- *Enforce password history* requires users to input a unique (previously unused) password when changing their password. This prevents users from reusing previous passwords.
- *Maximum password age* forces users to change the password after the specified time interval.
- *Password must meet complexity requirements* prevents using passwords that are easy to guess or crack. It forces passwords to include letters, symbols, and numbers, and also requires passwords of at least seven characters. However, you cannot configure a longer password length requirement with this policy.
- *Account lockout duration* determines the length of time the account is disabled (in minutes). When the time period expires, the account is unlocked automatically.

q_harden_auth_complex_03_secp8

You are teaching new users about security and passwords.

Which of the following is the BEST example of a secure password?

Answers:

- 8181952
- Stiles_2031
- JoHnSmITh
- ***T1a73gZ9!**

Explanation:

The most secure password is T1a73gZ9! because it is eight or more characters in length and combines uppercase and lowercase characters, special symbols, and numbers.

The least secure password is 8181952 because it appears to be a birthday. JoHnSmITh is not secure because it is still a name. Stiles_2031 is more secure but not as secure as random numbers and letters.

q_harden_auth_disable_accounts_secp8

You are the IT Security Manager for a multinational corporation. The company is undergoing a major restructuring, which includes employee layoffs, role changes, and new hires.

Given the situation, which of the following account maintenance practices would be the MOST effective in ensuring the security of your systems?

Answers:

- Implementing a policy that requires all employees to change their passwords immediately.
- ***Disabling the accounts of all employees who have been laid off and reviewing the access rights of remaining employees.**
- Requiring all employees to undergo a new round of security training.
- Implementing a policy that requires all employees to use a password manager.

Explanation:

Disabling the accounts of all employees who have been laid off is crucial to prevent unauthorized access and the most effective in this scenario. Reviewing the access rights of remaining employees is also important, as their roles may have changed during the restructuring. This option directly addresses the issue at hand and is the most effective way to maintain account security in this situation.

While requiring all employees to change their passwords immediately might seem like a good idea, it could lead to confusion and potentially weak password choices. Moreover, it doesn't address the issue of access rights for employees who have been laid off or whose roles have changed.

While security training is important, it's not the most effective immediate response to the situation. Training takes time and doesn't address the immediate risk of unauthorized access from laid-off employees or employees with changed roles.

While using a password manager is a good security practice, it doesn't address the immediate risks associated with the company's restructuring. It won't prevent unauthorized access from accounts that belong to laid-off employees or employees whose roles and access rights have changed.

q_harden_auth_history_secp8

You are configuring the Local Security Policy of a Windows system. You want to prevent users from reusing old passwords. You also want to force them to use a new password for at least five days before changing it again.

Which policies should you configure? (Select two.)

Answers:

- ***Enforce password history**
- Maximum password age
- ***Minimum password age**
- Password must meet complexity requirements

Explanation:

Set the *Enforce password history* policy to prevent users from reusing old passwords. Set the *Minimum password age* policy to prevent users from changing passwords too soon. Passwords must remain the same for at least the time period specified.

Use the *Maximum password age* policy to force periodic changes to the password. After the maximum password age has been reached, the user must change the password.

Use the *Password must meet complexity requirements* policy to require that passwords include letters, numbers, and symbols. This makes it harder for hackers to guess or crack passwords.

q_harden_auth_lockout_secp8

For users on your network, you want to automatically lock user accounts if four incorrect passwords are used within ten minutes.

What should you do?

Answers:

- Configure account expiration in user accounts.
- Configure day/time restrictions in user accounts.
- ***Configure account lockout policies in Group Policy.**
- Configure password policies in Group Policy.
- Configure the enable/disable feature in user accounts.

Explanation:

Account lockout disables a user account after a specified number of incorrect login attempts. The account lockout threshold identifies the allowed number of incorrect login attempts. The account lockout counter identifies a time period for keeping track of incorrect attempts (such as 10 minutes).

If account lockout locks a user account, use the unlock feature to allow login. Use the enable/disable feature to prevent or allow login using the user account.

Configure account (password) policies in Group Policy to enforce rules about the composition of passwords, such as minimum length, complexity, and history requirements. Use account expiration in a user account to disable an account after a specific day. Use day/time restrictions to prevent login during certain days or hours.

q_harden_auth_multifactor_secp8

You are the IT security manager for a rapidly growing tech company. The company has been using simple password authentication for all systems.

However, with the increasing number of employees and the sensitivity of the data being handled, you decide it's time to harden the authentication methods.

Which of the following steps would be the MOST effective in achieving this goal?

Answers:

- Implementing a policy that requires all passwords to be at least 8 characters long.
- ***Implementing multifactor authentication (MFA) for all systems.**
- Requiring all employees to change their passwords every 30 days.
- Implementing a policy that allows employees to use their personal email addresses for system logins.

Explanation:

Implementing multifactor authentication (MFA) is the most effective option. MFA requires users to provide two or more verification factors to gain access to a resource such as an application, online account, or a VPN. It adds an additional layer of security, reducing the likelihood of successful cyber attacks.

While having a policy that requires all passwords to be at least 8 characters long is a step in the right direction, it is not the most effective way to harden authentication methods. Longer passwords are generally more secure, but they can still be compromised, especially if they are not complex.

Requiring all employees to change their passwords every 30 days can lead to password fatigue, where users resort to using weak or reused passwords. While regular password changes can be part of a secure system, it is not as effective as implementing MFA.

Allowing employees to use their personal email addresses for system logins is not a good practice for hardening authentication. Personal email addresses can be compromised, which could lead to unauthorized access to company systems. It's better to use work-specific email addresses or other forms of identification for system logins.

q_harden_auth_password_expiration_secp8

The IT department at a small company is revamping its password policies to bolster security. The company wants to ensure employees follow best practices for creating and managing passwords.

The department aims to promote a secure environment by implementing password expiration policies.

Which method for password management is BEST to promote a secure environment by requiring users to change their passwords after a certain period?

Answers:

- ***Password expiration**
- Password complexity
- Password reuse prevention
- Password recovery via email

Explanation:

Implementing a password expiration policy requires users to change their passwords after a set period. This practice helps reduce the risk of unauthorized access from compromised passwords obtained in the past.

Password complexity requirements are essential for creating strong passwords, but they do not directly address the impact of password expiration on overall security.

Preventing password reuse is crucial to avoid using the same password for multiple accounts, but it is not directly related to the role of password expiration in enhancing security.

Password recovery via email involves users recovering forgotten passwords through email verification.

q_harden_auth_password_history_secp8

An employee at a company frequently recycles old passwords when prompted for a password change.

What feature of a password policy can prevent this?

Answers:

- Password length
- Password complexity
- Password age
- ***Password history**

Explanation:

The password history attribute keeps track of previously used passwords and prevents employee from using them again, discouraging password recycling.

Password length refers to the minimum (and sometimes maximum) length that a password should have. It does not prevent the reuse of old passwords.

Password complexity enforces rules like a mix of characters, numbers, and symbols. It does not prevent the reuse of old passwords.

Password age is the length of time an employee can use a password before it expires, and the employee must choose a new one. It does not prevent the reuse of old passwords.

q_harden_auth_reuse_secp8

You have just configured the password policy and set the minimum password age to 10.

What is the effect of this configuration?

Answers:

- ***Users cannot change the password for 10 days.**
- Users must change the password at least every 10 days.
- The password must contain 10 or more characters.
- The password must be entered within 10 minutes of the login prompt being displayed.
- The previous 10 passwords cannot be reused.

Explanation:

The minimum password age setting prevents users from changing the password too frequently. After the password is changed, it cannot be changed again for at least 10 days.

The maximum password age setting determines how frequently a password must be changed.

The minimum password length setting controls the minimum number of characters that must be in the password.

Password history is used to prevent previous passwords from being reused.

q_harden_auth_rshared_secp8

Upon running a security audit in your organization, you discover that several sales employees are using the same domain user account to log in and update the company's customer database.

Which action should you take? (Select two. Each response is part of a complete solution.)

Answers:

- ***Delete the account that the sales employees are currently using.**
- ***Train sales employees to use their own user accounts to update the customer database.**
- Implement a Group Policy Object (GPO) that restricts simultaneous logins to one.
- Implement a Group Policy Object (GPO) that implements time-of-day login restrictions.
- Apply the Group Policy Object (GPO) to the container where the sales user accounts reside.

Explanation:

You should prohibit the use of shared user accounts. Allowing multiple users to share an account increases the likelihood of the account being compromised. Because the account is shared, users tend to take security for the account less seriously. In the scenario, the following tasks need to be completed:

- The existing shared user account needs to be deleted. Until you delete the account, users can continue to use it for authentication. You could just change the password on the account, but there is a high chance that the new password would be shared again.
- Train sales employees to use their own user accounts to update the customer database. Ensure that these accounts have the level of access required for users to access the database.

Applying time-of-day login restrictions in a Group Policy object does not address the issue in this scenario.

q_harden_auth_shared_accounts_secp8

You are the IT security manager for a large corporation. The company has been using shared accounts for certain systems due to ease of access and convenience.

However, you are considering implementing a policy to prohibit the use of shared accounts.

Which of the following are valid reasons for this decision? (Select two.)

Answers:

- Shared accounts allow for easier password management.
- ***Shared accounts can lead to accountability issues.**
- Shared accounts reduce the need for individual user training.
- ***Shared accounts can compromise the principle of least privilege.**
- Shared accounts increase the speed of system access.

Explanation:

The following are valid reasons for prohibiting the use of shared accounts:

- Shared accounts can lead to accountability issues, making it difficult to track who did what. If an issue arises, it's nearly impossible to hold the appropriate person accountable because multiple people have access to the same account.
- The principle of least privilege states that users should only have access to the resources they need to do their jobs and nothing more. Shared accounts often have broad access rights, which can lead to unauthorized access to sensitive information.

Shared accounts may seem easier to manage because there is only one set of credentials to remember. However, they actually complicate password management because when one person leaves the company or changes roles, the password must be changed and communicated to all other users.

While it might seem that shared accounts reduce the need for individual user training, this is not a valid reason to use them. Each user should be trained on the systems they need to use to perform their job effectively and securely.

Shared accounts may seem to increase the speed of system access, but this is a short-term benefit. In the long term, they can lead to serious security risks, which can cause significant delays and costs if a breach occurs.

q_harden_auth_time_secp8

You have hired ten new temporary employees to be with the company for three months.

How can you make sure that these users can only log on during regular business hours?

Answers:

- ***Configure day/time restrictions in user accounts.**
- Configure account expiration in user accounts.
- Configure account policies in Group Policy.
- Configure account lockout in Group Policy.

Explanation:

Use day/time restrictions to limit the days and hours when users can log on.

Configure account expiration to disable an account after a specific date.

Use account policies in Group Policy to configure requirements for passwords.

Use account lockout settings in Group Policy to automatically lock accounts when a specific number of incorrect passwords are entered.

q_smartcard_auth_attack_secp8

Match each smart card attack on the left with the appropriate description on the right.

Answers:

- Accesses the chip's surface directly to observe, manipulate, and interfere with a circuit.
- Exploits vulnerabilities in a card's protocols or encryption methods.
- Captures transmission data produced by a card as it is used.
- Deliberately induces malfunctions in a card.

Explanation:

Smart cards are subject to the following weaknesses:

- Microprobing is the process of accessing a chip's surface directly to observe, manipulate, and interfere with the circuit.
- Software attacks exploit vulnerabilities in the card's protocols or encryption methods.
- Eavesdropping captures transmission data produced by the card as it is used.
- Fault generation deliberately induces malfunctions in a card.

q_smartcard_auth_contactless_secp8

John, a security analyst, is using a smart card to gain access to a secure server room. He simply waves his card near the card reader and the door unlocks.

Later, he uses the same card to log into his computer by inserting it into a card reader.

Based on this information, is John using a contact or contactless smart card?

Answers:

- Contact smart card, because he inserted the card into his computer's card reader.
- Contactless smart card, because he waved the card near the door's card reader.
- ***Both a contact and contactless smart card, because he used the card both by inserting it into a reader and by waving it near a reader.**
- Neither a contact nor contactless smart card, because smart cards cannot be used both ways.

Explanation:

John is using a smart card that has both contact and contactless capabilities. This type of card is known as a dual-interface smart card. It can be used by inserting it into a card reader (contact) and by waving it near a reader (contactless).

While John did insert the card into his computer's card reader, which is a characteristic of contact smart cards, this does not account for the fact that he also used the card by waving it near the door's card reader, which is a characteristic of contactless smart cards.

While John did wave the card near the door's card reader, which is a characteristic of contactless smart cards, this does not account for the fact that he also used the card by inserting it into his computer's card reader, which is a characteristic of contact smart cards.

While it may seem unusual, there are smart cards that have both contact and contactless capabilities. These are known as dual-interface smart cards. So, it is possible for a smart card to be used in both ways.

q_smartcard_auth_key_benefits_secp8

Which of the following are key benefits of using smart cards? (Select two.)

Answers:

- ***They provide tamper-resistant storage for a user's private key and other personally identifying information (PII).**
- They allow for unlimited data storage.
- They can be used to exploit vulnerabilities in a system's protocols.
- ***They isolate security-related operations from the rest of the system.**
- They can induce malfunctions in the card reader.

Explanation:

The following are key benefits of using smart cards:

- One of the key benefits of smart cards is that they provide tamper-resistant storage for a user's private key and other personally identifying information (PII). This makes them a secure method of storing sensitive information.
- Smart cards isolate security-related operations from the rest of the system. This means that even if a system is compromised, the operations carried out by the smart card remain secure.

While smart cards do have storage capabilities, they do not allow for unlimited data storage. The storage capacity of a smart card is limited by the size of the embedded memory chip.

Smart cards do not exploit vulnerabilities in a system's protocols. In fact, they are designed to enhance security by isolating security-related operations from the rest of the system.

Smart cards do not induce malfunctions in the card reader. They are designed to work seamlessly with card readers and any malfunctions would likely be due to a fault in the card reader itself, not the smart card.

q_smartcard_auth_key_weaknesses_secp8

Which of the following are key weaknesses of using smart cards? (Select two.)

Answers:

- ***They are susceptible to software attacks that exploit vulnerabilities in the card's protocols or encryption methods.**
- They are unable to store digital signatures, cryptography keys, and identification codes.
- ***They are vulnerable to eavesdropping that captures transmission data produced by the card as it is used.**
- They are incapable of performing their own cryptographic functions.
- They require a constant power supply to function.

Explanation:

The following are key weaknesses of using smart cards:

- One of the key weaknesses of smart cards is that they are susceptible to software attacks that exploit vulnerabilities in the card's protocols or encryption methods. This means that if a hacker can find a weakness in the card's security protocols, they may be able to gain unauthorized access to the card's data.
- Another weakness of smart cards is that they are vulnerable to eavesdropping that captures transmission data produced by the card as it is used. This means that if a hacker can intercept the data being transmitted by the card, they may be able to gain unauthorized access to the card's data.

Smart cards are actually capable of storing digital signatures, cryptography keys, and identification codes. This is one of their key features and not a weakness.

Smart cards are actually capable of performing their own cryptographic functions. This is one of their key features and not a weakness.

While smart cards do require power to function, they do not require a constant power supply. They are powered externally by the smart card reader when they are inserted into the reader. This is not considered a weakness of smart cards.

q_smartcard_auth_pki_secp8

Which technology is primarily used by smart cards to store digital signatures, cryptography keys, and identification codes?

Answers:

- Blockchain technology
- ***Public Key Infrastructure (PKI)**
- Secure Sockets Layer (SSL)
- Advanced Encryption Standard (AES)
- Hashing algorithms

Explanation:

Public Key Infrastructure (PKI) is the technology primarily used by smart cards. It allows for the storage of digital signatures, cryptography keys, and identification codes, providing secure and encrypted communication.

Blockchain technology is primarily used for creating decentralized digital ledgers for transactions. It is not typically used in the context of smart cards for storing digital signatures, cryptography keys, and identification codes.

Secure Sockets Layer (SSL) is a protocol used for securing data transmission over the internet. While it does involve encryption and can work with PKI, it is not the primary technology used by smart cards for storing digital signatures and keys.

Advanced Encryption Standard (AES) is an encryption standard used to secure data. While it may be used in conjunction with PKI for encryption purposes, it is not the primary technology used by smart cards for storing digital signatures and keys.

Hashing algorithms are used to convert data into a fixed size of numerical or alphanumeric characters. While they play a role in encryption and security, they are not the primary technology used by smart cards for storing digital signatures and keys.

4.6 Linux Users

As you study this section, answer the following questions:

- How do you create a user in Linux?
- Why shouldn't passwords expire too frequently?
- Which directory contains configuration file templates copied into a new user's home directory?
- Which command deletes a user and the user's home directory simultaneously?

In this section, you will learn to:

- Create a user account
- Rename a user account
- Delete a user
- Change your password
- Change a user's password
- Lock and unlock user accounts
- Configure Linux User Security and Restrictions
- Configure SELinux

This section helps you prepare for the following certification exam objectives:

Exam	Objective
CompTIA Security+ SY0-701	2.5 Explain the purpose of mitigation techniques used to secure the enterprise. • Hardening techniques ○ Default password changes 4.1 Given a scenario, apply common security techniques to computing resources. • Application security 4.5 Given a scenario, modify enterprise capabilities to enhance security.

Exam	Objective

	• Operating system security
	• SELinux
	
	4.6 Given a scenario, implement and maintain identity and access management.
	
	• Provisioning/de-provisioning user accounts
	• Password concepts
	  ○ Reuse
	  ○ Expiration

TestOut Security Pro	1.1 Manage identity 1.1.2 Manage Linux users and groups 1.2 Harden authentication 1.2.2 Manage account password

4.6.1 Linux User and Group Overview (Lesson Video)

Transcript:

In this video, we're going to discuss Linux users and groups. First, when you're working with Linux, it's important to understand that it's a true multi-user operating system. Each user account has their own unique, customizable computing environment. When user accounts are stored locally, Linux stores the user, group, and password information in three separate files on the local file system in the /etc directory. We'll discuss each of these files in this lesson.

The first file is the passwd file. The password file is named passwd, and it's stored in the /etc directory. This file contains the user account information for your system; this is where your users are defined. But don't let the filename confuse you. This file doesn't contain any password information, only user account information. Passwords are stored in another file that we'll look at in a bit.
You may hear people still refer to this file as the password file because in the early days of UNIX, passwords were stored in here alongside the usernames. But, as you can imagine, this presented a huge security risk, so this file no longer contains any passwords. To avoid confusion, I'll call this the passwd file.
So, now, the passwd file is where all the user accounts are stored. Each user account on a system is represented by a single line called an account record. An account record is composed of several fields, each separated by a colon.
The first field is the username. The second is the password field. The third is the user ID field. Then there's the group ID field, the full name field, the home directory field, and finally, the shell field.
Let's look at an example of each field. The username field contains the username the user will use to log in to the system. For example, for this record, the user account is zday. Next, we have the password field. Since this is a remnant of when passwords used to be stored in this file, you'll only see an X in this field. Now passwords are stored in the shadow file, which we'll talk about in a bit. Next is the UID field. This contains the user ID that's assigned to the user account. This user account is assigned a UID number of 1001.
Then we have the group ID field, which references the group ID number of the user's default group. In Linux, a single user account can be a member of several different groups, but by default, a user is always assigned to one group, the default group. This is almost always the Users group, which has an ID of 100.
Next, we have the full name field, which just contains the user's full name. The next field specifies the user's home directory. And finally, the default shell field specifies which shell is going to run for the user by default. Most distributions set the default shell to /bin/bash.

It's important to understand that the passwd file contains two different types of users. First, there's the standard user accounts. These accounts are used to log in to the system, such as the zday account we just saw.
The second type of accounts are the system user accounts. These accounts can't be used to log in to the system. They're used by services or daemons that are running on the system. This is because Linux uses groups, users, and permissions to control privileges. For a service or daemon to be able to read from or
write to the file system, it needs to have a user account. So, if you ever open the passwd file and wonder why there are so many users that you never created, it's because the passwd file contains both standard user accounts.
Now let's talk about the shadow file, which is where passwords are stored these days.
The shadow file is linked to the passwd file. Each user account defined in your passwd file has a corresponding entry in the shadow file. As with the passwd file, each user account is represented by a single line in the shadow file called a record, which is composed of several different fields separated by colons.
Here's an example of a single record in the shadow file.
First, we have the username field, which is the same username that's defined in the passwd file. This is what links the two records together. Next, we have the password field. Depending on the type of user account you're looking at, there are a few things you can see in the password field.
For example, if the record is for a standard user account, the password field will contain a string of text. This is the user's actual password in encrypted format. Theoretically, it's possible to crack this encrypted password if someone were to gain access to this file. But it's extremely difficult to do, and it would take a very, very long time.
If the record is for a system user account, the password field will contain an asterisk. Remember, system user accounts can't be used to log in to the system. The asterisk indicates that this account is disabled, which prevents it from being able to authenticate to the system.
There's one more thing you might see in the password field: a blank entry. Nothing. This means that the user account doesn't have a password and doesn't require one to log in to the system. As you can imagine, this presents a huge security hole. A user account should always have either an encrypted password or an asterisk, not a blank entry.
The next field is the last modified field. This field displays the numbers of days since January 1st, 1970 that the password was last changed. So, when you see a huge number here, just remember that it's counting all the days between January 1st, 1970, and the day the password was last changed.
Next, we have the minimum days field. This field defines the minimum number of days that need to pass before a password can change. Usually, this is set to zero, which means the password can be changed any time. But if you want to make it so users need to keep the same password for at least a week, you could put a seven in this field.
The next field is the maximum days field. This field defines the maximum number of days a password can be used. For example, if you want users to change their password after 90 days, you would enter '90' in this field, or you can set passwords to never expire by entering â€˜99999' here.
Next, we have the days warning field. This field defines when a user will be warned that their password is about to expire. This field is usually set to five or seven days.
The next field defines the number of days to wait after a password is expired to disable the account. This field is usually set to -1, which disables this functionality. But if you want to disable an account if its password isn't changed after it expires, then you can enter a number, 3 for example.
And finally, we have the expire field. This field defines the number of days since January 1st, 1970, that must pass until the account is automatically disabled. By default, this field is blank, which means this functionality is disabled. But if you want an account to be automatically disabled on a specific date, you need to figure out the number of days between it and January 1st, 1970, and then enter that number. And don't worry, there are several tools available that can do this calculation for you.
Now, because the passwd and shadow files work together, they need to stay synchronized. The main way these files become out of sync is when an administrator uses a text editor to make changes to one of the files, but forgets to make the changes to the other, such as changing a username. If the files don't match, you've got a problem.
To avoid this, manage user accounts using the password and user management utilities that are provided by the operating system. Avoid using a text editor. If a problem does occur, there are few commands you can use to compare the passwd file and shadow file, such as pwck, and then re-synchronize the files if they don't match.
Now, let's look at the third file, the /etc/group file. Like most operating systems,
Linux uses groups to help ease system management. For example, instead of managing the privileges of each individual user, you can manage the privileges of a single group and then assign user accounts to that group.
Now, any changes made to the group will be automatically applied to the users. If you're managing hundreds of users, groups make your job a lot easier. Groups on a Linux system are defined in the /etc/group file. And the structure of the group file is similar to the passwd and shadow files.
Each line in the group file is a single record that defines one group on your system, and each record is composed of four fields separated by colons. The first field is the group field. It specifies the group's name. In this example, the name of

the group is sales. The second field is the password field, which specifies a password for the group. This field is rarely used, and in most cases it'll contain an X, which means no password is set. The third field is the group ID number, or the GID. In this case, the GID is 33. And the last field is a list of users who are members of the group. In this example, you see that zday and rnelson are both members of the sales group.
Keep in mind that some Linux distributions use an additional group file to store group passwords. This works in a similar way to the passwd and shadow files. With this model, group passwords are stored in the gshadow file. Like the group file, the gshadow file has corresponding records and fields that define each group. In the gshadow file, you'll see fields that define the group name, the password, the group admins, and the group members.
So that's how Linux users and groups work on a Linux system. In this lesson, we talked about user account storage. First, we looked at the /etc/passwd file, which contains user account information. Then we looked at the shadow file, which contains user passwords and password settings. And finally, we looked at the group file, where groups and group members are defined.

4.6.2 Managing Linux Users (Demo Video)

Transcript:

In this demonstration, we're going toÂ talk about managing Linux user accounts.Â As a Linux administrator, there will be times whenÂ you have to add, remove, or modify user accounts.Â Let's begin by looking at the User AddÂ utility.

As a root user, you type â€˜useradd' followed byÂ any options you might want and then the username.Â It's important to note that if you create a userÂ in the shell prompt with useradd, it will automatically use the default valuesÂ contained and the /etc/default/user add file.
Let's look at that file right now withÂ 'less /etc/default/useradd'.Â Notice that the useradd commands use the default values. First, look at the defaultÂ home directory, specified as the /home directory.
That's where the user's default profile, or default directory,Â will be created. There's no expiration date set by default for the account.Â The shell is bin/bash, and theÂ skeleton file is etc/skel.
This is useful if you have specific files or foldersÂ that you want to be in each new user's home directory.Â You can simply place them in the skeletonÂ directory, and then they're automaticallyÂ created in the new user's home directory.
We can see here, at the bottom, that a mailÂ spool for the user account will also be created.Â You can go into this file usingÂ the VI editor and change these default values if you need to.
For example, if you want the home directory to be inÂ a different location by default, you can set thatÂ default by typing â€˜useradd -D' at the shell prompt.Â You need to also be aware that the less /etc/login.defsÂ file is used to configure the values that can beÂ used for the group ID and the user ID.
If we hit Enter and scroll down,Â we can see here that the values for the group ID andÂ the user ID are specified, so you can see the minimumÂ value for the user ID on this Linux version is 1000.Â Also, for the group ID, the minimum is set to 1000.Â Let's exit out of that.
Now let's talk about useradd.Â Like I said before, you can override theÂ default values using command line options. We'll take a look at the man page for useradd, â€˜man useradd'. This will show you all the available options for the useradd command. A few examples are -c to specify a comment for the user's full name, -g (lowercase) to add a single primary group, and -G (uppercase) to add supplementary groups separated by commas.
Let's look at an example.Â Suppose we want to create a user namedÂ ksanders whose full name is Kim Sanders.Â We want to create a home directory, and we want toÂ specify the user's name as we create the account.Â Let's go ahead and type in 'sudo useradd'.
Now we want to use the -c optionÂ to specify the user's full name.Â We're going to put in â€˜"Kim Sanders"' in quotes.Â Then we're going to use the â€˜-m' option to create the user'sÂ home directory and specify the username as â€˜ksanders'.Â Press Enter.
After suppling the sudo password to add the account, we can verify that was created by looking at our etc/passwd file.Â If we scroll down, we can see a few things here.Â You can see the group and user ID, 1002, 1002.We can see the full name, Kim Sanders, and we can alsoÂ see the ksanders folder within the home directory.
ksanders doesn't have a password yet.Â On Linux, if the user account doesn't haveÂ a password, then the password is locked.Â We can verify this by typing in 'sudo passwdÂ -S' followed by the username, 'ksanders'.
Now we can see this LK, which tells usÂ that the account is locked.Â So, before the user can log in, we have toÂ enable the account by adding a password.

We need to type 'sudo passwd'Â followed by the user account, 'ksanders'.Â Hit Enter.Â It wants us to create a password.Â We're going to type '1234' just for now. This is just a test account, so that password is fine.Â Retype the password, '1234'.Â We get a warning about the password length, but the password updates successfully.Â Now we want to verify that, so we'reÂ going to retype â€˜sudo passwd-S ksanders'.
You can see now that this has changed to a PS from an LK.Â That indicates that a passwordÂ has been unlocked and is now set up for this account.Â Now this user can actually log in to this profile.
From time to time, you may need to modify an existing user.Â This is done with the usermod command. usermod's options are prettyÂ much the same as useradd's.
For example, let's say we entered theÂ wrong full name for the ksanders account.Â Her name is actually Kimberly.Â We can go ahead and change this by typing 'sudoÂ usermod - c' and then putting the correct name, 'Kimberly Sanders',Â closed single quotations, and then the user account, 'ksanders'.
Now we want to verify those changes.Â We're going to go to 'lessÂ /etc/passwd' and scroll to the bottom.Â We can see that 'Kim Sanders'Â has actually changed to 'Kimberly Sanders'.
You can use other options with the usermod command to changeÂ user account information, such as the username itself, theÂ user ID, the default group, and the home directory.
The last thing we want to look at isÂ the user delete, or userdel, command.Â This command is used to remove an account.Â We're going to remove the ksanders account.
There's only one option we can use withÂ userdel, and that's the -r option.Â By default, if you don't use the -r option,Â the userdel command won't delete theÂ user's home directory from the file system. This is because there might be intellectualÂ property in that directory that you need toÂ keep, even if you delete the user account.Â But if you do want to delete the home directory alongÂ with the user account, you can use the -r option. Let's go ahead and type this in, 'sudo userdelÂ ksanders -r'. We're not going to hit Enter justÂ yet because I want to show you another way of addingÂ and maintaining user accounts.
Sometimes, depending on the distribution, you can actually do this through aÂ GUI or graphical user interface within Linux.Â Some Linux systems have them, and some don't.Â Sometimes you can download them.Â This system already has one. Let's go ahead and click on the dropdown by the power button and click Settings. Scroll down to Details and click Users.Â Here's our Kim Sanders account. It looks like the name didn't update to Kimberly in the GUI, but we do know it changed because we just saw that in the command line.Â If I were to unlock this, I could go in andÂ manage this account.
Here, I can do things such change the account type or reset the password.Â It'll show me my login history as well.Â I'm not actually going to do anything from here,Â but I did want to show you that because I want toÂ show you how the account is actually removed.
If I go ahead and I run thisÂ command, now the user is deleted.Â If we go back and look at the â€˜/etc/passwd' fileÂ and scroll down, you can see the account isÂ deleted.
That's it for this demonstration.Â In this demo, we talked about managingÂ Linux users using the shell prompt.Â We looked at the useradd command, the usermodÂ command, the passwd command, and the userdel command.
We also looked at the graphic interface thatÂ some Linux systems will use, and we looked atÂ other options for each command.

4.6.3 Linux User Commands and Files

This lesson covers the following topics:

- User files
- User management commands

User Files

Linux is highly flexible regarding where user and group information is stored. The options for storing the data are:

- Local file system.
- LDAP-compliant database.
- Network Information System (NIS). NIS allows many Linux computers to share common user accounts, group accounts, and passwords.

- A Windows domain.

When files are stored in the local file system, the following files are used:

File	Description
/etc/passwd	The /etc/passwd file contains the user account information. Each user's data is stored in a single line on this file. There are two types of accounts in a Linux system: • Standard accounts (these are user accounts). • System user accounts (these are used by services).
/etc/shadow	In Linux, local user account names are stored in /etc/passwd. When a user logs in to a local interactive shell, the password is checked against a hash stored in /etc/shadow. There are corresponding entries in both files, and they must stay synchronized. The system provides password and user management utilities, allowing you to edit and keep the files synchronized. You can use the following commands to identify errors and synchronize the files: • **pwck** verifies each line in the two files and identifies discrepancies. • **pwconv** adds the necessary information to synchronize the files. Interactive login over a network is typically accomplished using Secure Shell (SSH). With SSH, the user can be authenticated using cryptographic keys instead of a password. A pluggable authentication module (PAM) is a package for enabling different authentication providers, such as smart-card log-in. The PAM framework can also be used to implement authentication to network directory services.
/etc/group	As with Active Directory, groups can be used to simplify user access to network resources. The /etc/group file contains information about each group.

Be aware of the following configuration files when managing user accounts:

File	Description
/etc/default/useradd	The /etc/default/useradd file contains default values used by the useradd utility when creating a user account, including: • Group ID. • Home directory. • Account expiration. • Default shell. • Secondary group membership.
/etc/login.defs	The /etc/login.defs file contains: • Values used for the group and user ID numbers. • Parameters for password encryption in the shadow file. • Password expiration values for user accounts.

File	Description
/etc/skel	The /etc/skel directory contains a set of configuration file templates that are copied into a new user's home directory when it is created, including the following files: • .bashrc • .bash_logout • .bash_profile • .kshrc

User Management Commands

Although it is possible to edit the /etc/passwd and /etc/shadow files manually to manage user accounts, doing so can disable your system. Instead, use the following commands to manage user accounts:

Command	Command Function
useradd	Create a user account. The following options override the settings as found in /etc/default/useradd: • **-c** adds a description for the account in the GECOS field of /etc/passwd. • **-d** assigns an absolute pathname to a custom home directory location. • **-D** displays the default values specified in the /etc/default/useradd file. • **-e** specifies the date on which the user account will be disabled. • **-f** specifies the number of days after a password expires until the account is permanently disabled. • **-M** defines the secondary group membership. • **-m** creates the user's home directory (if it does not exist). • **-n** does not create a group with the same name as the user (Red Hat and Fedora, respectively). • **-p** defines the encrypted password. • **-r** specifies that the user account is a system user. • **-s** defines the default shell. • **-u** assigns the user a custom UID. This is useful when assigning ownership of files and directories to a different user.
passwd	Assign or change a password for a user: • **passwd** (without a username or options) changes the current user's password. • Users can change their own passwords. The root user can execute all other **passwd** commands. Be aware of the following options: • **-S** username displays the status of the user account. LK indicates that the user account is locked, and PS indicates the user account has a password. • **-l** disables (locks) an account. This command inserts a !! before the password in the /etc/shadow file, effectively disabling the account. • **-u** enables (unlocks) an account. • **-d** removes the password from an account.

Command	Command Function
	• **-n** sets the minimum days before a password can be changed. • **-x** sets the number of days before a user must change the password (password expiration time). • **-w** sets the number of days before the password expires that the user is warned. • **-t** sets the number of days following the password expiration that the account will be disabled.
usermod	Used to modify an existing user account; usermod uses several of the same switches as useradd. Be aware of the following switches: • **-c** changes the description for the account. • **-l** renames a user account. • **-L** locks the user account. This command inserts a ! before the password in the /etc/shadow file, effectively disabling the account. • **-U** unlocks the user account.
userdel	Remove the user from the system. Be aware of the following options: • **userdel** [username] (without options) removes the user account. • **-r** removes the user's home directory. • **-f** forces removing the user account even when the user is logged into the system.

If you are logged in as the root user, the commands in the table can be run by typing the applicable command and its options. However, if you are not logged in as the root user, you must use the **sudo** or **su** command to gain the permissions required. For example, to create a new user named Kim Sanders, you would run: **sudo useradd -c "Kim Sanders" -m ksanders**

4.6.4 Create a User Account (Simulation)

Scenario

The VP of marketing has told you that Paul Denunzio will join the company as a market analyst in two weeks. You need to create a new user account for him.

You are logged in as root, so the **sudo** command is unnecessary.

In this lab, your task is to:

- Create the **pdenunzio** user account.
  - Include the full name, **Paul Denunzio** , as a comment for the user account.
- Set **eye8cereal** as the password for the user account.
- When you are finished, view the **/etc/passwd** file to verify the creation of the account.
- Answer the question.

Explanation

Complete this lab as follows:

1. Create the Paul Denunzio account and comment.
    a. From the Favorites bar, select **Terminal** .
    b. From the Linux prompt, type **useradd -c "Paul Denunzio" pdenunzio** and press **Enter** .
2. Create a password for Paul.
    a. Type **passwd pdenunzio** and press **Enter** .
    b. Type **eye8cereal** as the password and press **Enter** .
    c. Retype **eye8cereal** as the password and press **Enter** .
3. Verify that the account was created.
    - Type **cat /etc/passwd** and press **Enter** .
4. Answer the question.
    a. From the top right, select **Answer Questions** .
    b. Select the correct answer.
    c. Select **Score Lab** .

4.6.5 Rename a User Account (Simulation)

Scenario

Brenda Cassini (bcassini) was recently married. You need to update her Linux user account to reflect her new last name, Palmer. You are currently logged in as the root account, so you will not need to use the sudo command to get permissions to perform the required tasks.

In this lab, your task is to open Terminal and then use the **usermod** command to:

- Rename Brenda's user account to **bpalmer** .
- Change Brenda's comment field to read **Brenda Palmer** .
- Change and move Brenda's home directory to **/home/bpalmer** .
- When you're finished, view the **/etc/passwd** file and **/home** directory to verify the modification.

Explanation

Complete this lab as follows:

1. Rename the bpalmer account and move her home directory.
    a. From the Favorites bar, select **Terminal** .
    b. From the Terminal prompt, type **usermod -l bpalmer bcassini -m -c "Brenda Palmer" -d /home/bpalmer** and press **Enter** .
2. Verify account modification.
    a. Type **cat /etc/passwd** and press **Enter** .
    b. Find the line that shows that Brenda's account has been changed.
    c. Type **ls /home** and press **Enter** to verify that the account was modified.
    Notice that the home directory for Brenda is now bpalmer.

4.6.6 Delete a User (Simulation)

Scenario

Terry Haslam (thaslam) was dismissed from the organization. His colleagues have harvested the files they need from his home and other directories. Your company security policy states that upon dismissal, the user's accounts should be removed in their entirety.

In this lab, your task is to:

- Delete the thaslam user account and home directory from the system.
- When you're finished, view the **/etc/passwd** file and **/home** directory to verify the account's removal.

Explanation

Complete this lab as follows:

1. Delete the Terry Haslam account and home directory.
    a. From the Favorites bar, select **Terminal** .
    b. At the prompt, type **userdel -r thaslam** and press **Enter** .
2. Verify the account's removal.
    a. Type **cat /etc/passwd** and press **Enter** .
    b. Type **ls /home** and press **Enter** to verify the account was removed.

4.6.7 Change Your Password (Simulation)

Scenario

You use a special user account called Administrator to log on to your computer. However, you think someone has learned your password. You are logged on as Administrator.

In this lab, your task is to change your password to **r8ting4str** . The current Administrator account uses **7hevn9jan** as the password.

As you type in the password, the cursor will not move. Continue entering the password anyway.

Explanation

Complete this lab as follows:

1. Change your password.
    a. From the Favorites bar, select **Terminal** .
    b. At the prompt, type **passwd** and press **Enter** .
    c. When prompted, enter **7hevn9jan** and press **Enter** . This is the current password.
    d. At the *New password* prompt, enter **r8ting4str** and press **Enter** .
    e. Retype **r8ting4str** as the new password and press **Enter** .

4.6.8 Change a User's Password (Simulation)

Scenario

Salman Chawla (schawla) forgot his password and needs access to the resources on his computer. You are logged on as wadams. The password for the root account is **1worm4b8** .

In this lab, your task is to:

- Change the password for the schawla user account to **G20oly04** (0 is a zero).
- Make sure the password is encrypted in the shadow file.

Do not use the **usermod -p** command to change the password, as this stores the unencrypted version of the password in the /etc/shadow file.

Explanation

Complete this lab as follows:

1. Change Salman Chawla's password.
    a. From the Favorites bar, select **Terminal** .
    b. At the prompt, type **su -c "passwd schawla"** , then press **Enter** .
    c. Type **1worm4b8** , then press **Enter** . This is the password for the root user.
    d. At the *New password* prompt, type **G20oly04** , then press **Enter** . This is the new password for the schawla user account.
    e. At the *Retype new password* prompt, type **G20oly04** , then press **Enter** .

4.6.9 Lock and Unlock User Accounts (Simulation)

Scenario

Every seven years, your company provides a six-week sabbatical for every employee. Vera Edwards (vedwards), Corey Flynn (cflynn), and Bhumika Kahn (bkahn) are leaving today. Maggie Brown (mbrown), Brenda Cassini (bcassini), and Arturo Espinoza (aespinoza) are just returning.

The company security policy mandates that user accounts for employees gone for longer than two weeks be disabled.

In this lab, your task is to:

- Lock the following user accounts:
    - **vedwards**
    - **cflynn**
    - **bkahn**
- Unlock the following user accounts:
    - **mbrown**
    - **bcassini**
    - **aespinoza**
- When you're finished, view the **/etc/shadow** file to verify the changes.

Explanation

Complete this lab as follows:

1. Lock the applicable accounts.
    a. From the Favorites bar, select **Terminal** .
    b. At the prompt, type **usermod -L vedwards** or **passwd -l vedwards** and press **Enter** .
    c. Type **usermod -L cflynn** or **passwd -l cflynn** and press **Enter** .
    d. Type **usermod -L bkahn** or **passwd -l bkahn** and press **Enter** .
2. Unlock the applicable accounts.
    a. Type **usermod -U mbrown** or **passwd -u mbrown** and press **Enter** .
    b. Type **usermod -U bcassini** or **passwd -u bcassini** and press **Enter** .
    c. Type **usermod -U aespinoza** or **passwd -u aespinoza** and press **Enter** .
3. Verify your changes by typing **cat /etc/shadow** and pressing **Enter** .
   The inclusion of the exclamation point (**!**) in the password field indicates whether the account is disabled.

4.6.10 Linux User Security and Restrictions (Lesson Video)

4.6.11 Configuring Linux User Security and Restrictions (Demo Video)

Transcript:

In this demonstration, we're going to talk about configuring user restrictions. We're going to look at this topic from three different aspects: password aging, setting login limits, and then setting user limits with the ulimit command.

Let's begin by talking about password aging. In today's security environment, you need to be very careful that you configure your passwords to expire after a set period of time. This is called password aging. The key thing to remember here is that the longer a user has the same password, the more it likely it is to be compromised. To prevent this, you need to configure aging for your user password. This is done with the chage command.
Let's look at the 'chage' man page. The syntax for using chage is to enter the chage command followed by a series of options and then the user account that you want to apply those options to. Some of the more useful options you can use are listed right here. First, we have the lowercase -m option, which specifies the minimum number of days between password changes. You also have the uppercase -M option, which specifies the maximum number of days between password changes. And then we have the -w option that specifies the number of warning days a user gets before the password change is required. Go ahead and exit out of the man page.
Let's work through an example. I'm going to enter 'chage' at the shell prompt as my root user. Then I'm going to specify the capital '-M' option to set the maximum number of days between password changes. Let's set that to two months. For many organizations, that would be way too long. A lot of organizations force password changes every 30 days. Let's specify '-w' to specify that a warning is given seven days before the password is about to expire, so the user has plenty of time to make the change before the password actually expires.
Then we must specify who we want to apply this change to. Let's apply it to our rmckay user account. The password is set to expire for the rmckay user in 60 days. Let's use the 'tail' command to verify this by viewing the /etc/shadow file. Look at the very end of the file. Take a look at the rmckay user account. We can see here that the maximum number of days between password changes is 60, and the rmckay user will get seven warning days to change their password before it expires.
The next thing we need to discuss is configuring user limits. Understand that you can configure limits for how many times a user may log in, how much CPU time they use, how much memory they can use, and so on. We configure these limits in the '/etc/security/limits.conf' file. The syntax for this file is shown here. First, we specify the domain. The domain, as noted here, can be a user, or it could be a group.
If you want to use a group, you have to put this '@' sign in front of the group name to indicate that it's a group, or you can use a wild card-- listed here--to apply it to everybody. Scroll down a little bit so we can see more.
Next, we specify the type. As noted here, the type can have two different values. We can either specify a hard limit that can never be exceeded, or we can specify a soft limit that can be exceeded, but just temporarily. Then we specify the item. This is the particular thing that's going to be limited. As you can see down here, we have lots of different options for how we can limit what the item can be.
We can specify core to limit the size of the core dump files. We can specify data to configure a maximum data size and memory for the user's programs. We can specify fsize to restrict the maximum file size. We can specify nofile. We can specify the maximum number of open files. We can specify rss to set the maximum resident set size and memory. We can specify stack to set the maximum stack size. We can specify cpu and set the amount of CPU time that can be used by a single process in minutes. We can specify nproc to specify the number of concurrent processes that will be allowed. Or we can come down here and specify max logins to specify the maximum number of simultaneous logins that we allow for this user. We can also specify priority if we want to, to specify the priority to run user processes with, for this particular user account. Once we specify the item, we scroll back here, and then we specify the value for that item. This is the limit that we're going to configure.
With this in mind, let's go down here, and let's create a new limit. We're going to configure a limit for our rmckay user. I'll enter 'rmckay' for our domain. Next, we want to specify a hard limit, and the item we want to limit is our CPU time. This is the maximum amount of CPU time that a single process run by this user can consume. We must specify how much that is. We do that in minutes. We'll specify 10 minutes. Lets save this by typing "wq!" and hitting Enter. To apply the change, we have to reboot the system.

The last thing we're going to look at the in this demonstration is the ulimit command. To be honest, I don't really care much for the ulimit command. In my experience, it's not as useful as the limits.conf file that we just looked at. The ulimit command does allow you to configure limits on system resources on a per-user basis, much like we did in the limits.conf file. However, be aware that any limits that you configure with ulimit will only affect programs that are launched from within the shell prompt. If, on the other hand, the user was to come over here and launch a graphical application on the desktop, then the limits you specify with ulimit aren't applied. That's why I don't really care for it.
The syntax for ulimit is to enter 'ulimit' followed by the options you want to use and then the limit that you want to specify. There are many different limits you can configure with ulimit. Take a look at the ulimit man page to see a full list of what you can do. For our purposes today, let's just run 'ulimit -a' to, first of all, view the current limits for my user account. You can see what they are right here.
You can also use ulimit to set a limit. Let's set a basic limit. Let's suppose we want to set a soft limit of 100 concurrent processes for my user account. To do this, we would enter' ulimit-s' to set a soft limit. If we wanted to, we could use -h to set a hard limit. Then we have to specify which limit we want to use. We'll use the '-u' option to set the maximum number of processes available to the user. How did I know that that's the right option to use? I looked at the man page. That's what you should do as well. Then we must set that to a specific value. Let's enter '100'. My user account can only have a maximum of 100 concurrent processes. Enter, and the limit is applied.
If we run 'ulimit -a' again, we see that my max user processes have dropped from 7,084 down to 100, which, depending on how the system is being used, would not be anywhere near enough. That's essentially how you use ulimit. Basically, you use ulimit to constrain what users can do so you don't end up with one user hogging all the system resources and not allowing other users on the system to access them.
That's it for this demonstration. In this demo, we talked about how to set up user restrictions on limits. First, we looked at password aging. We looked at login limits. Then we ended this demonstration by looking at the ulimit command.

4.6.12 Configure SELinux (Demo Video)

Transcript:

In this lesson, we're going to review SELinux, or Secure Linux. SELinux allows for a more granular approach to securing Linux from the outside world. This version is installed on most RHEL- or CentOS-based distributions by default. In order to properly configure SELinux, we need to elevate to the root account.

Let's do the sestatus command to see if SELinux is running already. We see the current mode is enforcing. We'll go over that in a little bit.
We use the getenforce command to view the current SELinux mode. This lets us know if the system is enforcing the right properties. We can change enforcement modes with this setenforce command. Type setenforce 0 to change the mode to permissive. This will turn off the protections and controls of SELinux. When we run getenforce again, it's configured to permissive. Type setenforce 1 to change the mode back to enforcing. Now, these changes are temporary. Once we reboot, SELinux will load the configurations in the SELinux config file.
Let's change directories to /etc/selinux and open the config file. We see that SELinux is enforcing, and the Linux type is targeted. This means SELinux will only monitor certain processes, and those processes will be protected. The minimum is a modification of the targeted policy. Once selected, they're protected. And MLS means multi-level security protection. We're just going to look at the targeted type in this demonstration.
Let's exit our text editor. We're going run a program called getsebool. Getsebool is Boolean, meaning that it's either on or off. Now that's add -a for "show all". We see that there are many different Boolean settings for different processes. We're going to look only at the samba processes. Let's run getsebool -a | grep samba to filter only samba processes. The process we're looking to manage here is samba_enable_home_dirs.
So, samba is the process that allows Linux to share files with Windows devices by appearing like a Windows file server. We don't want to enable home directories to be advertised on samba. Let's run setsebool samba_enable_home_dirs=off. Okay, when we rerun the filtered getsebool command, we see that samba_enable_home_dirs is now off.
Again, this is a temporary setting. If we wanted to make the changes permanent, we'd type the same setsebool command but with a dash capital P for "permanent" and then samba_enable_home_dirs=off. Now we press Enter, and when the system reboots, samba home directories will be set to off. Let's move on.
So, files take on different permissions with SELinux. Let's switch to the home directory and use touch file1 to create a file. Let's also see some additional SELinux components. Run ls -lZ file1. We see that the permissions are standard, with Read/write for the user and Read for the group. And then it's Read for everybody else. It's owned by root, and it's owned

by a group called root as well. Now, though, we now have additional information. We have the user type, the role base, and the type of file that it is.
We can change this new information if we want. You might do this because you want to alter who can change the file or something like that. It gives us an additional granularity of control. To do this, you'd use the change context command, called chcon. We're going to change the type from admin_home to a user_home type.
Let's type chcon -t. Now, the -t is what changes the file type, not the role or user type. Okay, continue typing user_home_t file1. We identify the file type and the file we're making the change to. Let's run ls -lZ for file1, and we see that we've changed the type from admin_home to user_home.
Let's say that the changes ended up being a mistake. We could restore the context with a command that changes everything back. We'd run restorecon, specify the file name, and it'd restore the original settings. When we run ls -lZ file1 again, we see the changes.
And that's all for now. In this demonstration, we showed you some SELinux commands, including sestatus, getenforce, and setenforce. Then we modified some Boolean values with getsebool and setsebool. And we also used chcon to change and restore context.

4.6.13 Linux User Security and Restriction Facts

This lesson covers the following topics:

- User security
- User security commands

User Security

When considering user security, keep the following in mind:

- Users should be trained to use secure passwords. Secure passwords use numbers and letters and are more than seven characters in length.
- Passwords should expire periodically but not too often.
- Administrators can limit the resources that the user can access.

User Security Commands

The following table describes Linux commands used to promote user security and restrictions:

Command	Description
chage	Set user passwords to expire. Be aware of the following options: • **-M** sets the maximum number of days before the password expires. • **-W** sets the number of days before the password expires that a warning message displays. • **-m** sets the minimum number of days that must pass after a password has been changed before a user can change the password again.
ulimit	Limits computer resources used for applications launched from the shell. Limits can be hard or soft limits. Soft limits can be temporarily exceeded up to the hard limit setting. Users can modify soft limits, but only the root user can modify hard limits. Options include:

	• **-c** limits the size of a core dump file. The value is in blocks. • **-f** limits the file size of files created using the shell session. The value is in blocks. • **-n** limits the maximum number of files that can be open. • **-t** limits the amount of CPU time a process can use. This is set in seconds. • **-u** limits the number of concurrent processes a user can run. • **-d** limits the maximum amount of memory a process can use. The value is in kilobytes. • **-H** sets a hard resource limit. • **-S** sets a soft resource limit. • **-a** displays current limits. The default shows soft limits.

4.6.14 Practice Questions (Section Quiz)

q_linux_usr_cmds_audit_secp8

You have performed an audit and found an active account for an employee with the username *joer*. This user no longer works for the company.

Which command can you use to disable this account?

Answers:

- ***usermod -L joer**
- usermod -l joer
- usermod -d joer
- usermod -u joer

Explanation:

Use **usermod -L joer** to lock the user's password. Doing so disables the account.

The **usermod -l joer** command changes the account's login name.

The **-d** flag is used for changing the account's home directory.

The **-u** flag is used for changing the account's numeric ID.

q_linux_usr_cmds_login_defs_03_secp8

What information does the /etc/login.defs file contain in a Linux system?

Answers:

- ***User and group ID numbers**
- User account passwords
- List of all installed software
- Network configuration details

Explanation:

User and group ID numbers is the correct answer. The /etc/login.defs file contains values used for the group and user ID numbers. It also includes parameters for password encryption in the shadow file and password expiration values for user accounts.

User account passwords are not stored in the /etc/login.defs file. They are stored in the /etc/shadow file.

The /etc/login.defs file does not contain a list of all installed software. This information can be found in other locations, such as the package manager database.

Network configuration details are not stored in the /etc/login.defs file. These details are typically found in files within the /etc/network directory.

q_linux_usr_cmds_user_01_secp8

One of your users, Karen Scott, has recently married and is now Karen Jones. She has requested that her username be changed from kscott to kjones with no other values changed.

Which of the following commands would accomplish this?

Answers:

- ***usermod -l kjones kscott**
- usermod -l kscott kjones
- usermod -u kjones kscott
- usermod -u kscott kjones

Explanation:

Use the **usermod** command to modify user settings. Use the **-l** flag to signal a change to the username. The correct syntax requires the new username value be given, followed by the old username.

The **-u** flag changes the UID number.

q_linux_usr_cmds_user_02_secp8

An employee named Bob Smith, whose username is bsmith, has left the company. You have been instructed to delete his user account and home directory.

Which of the following commands would produce the required outcome? (Select two.)

Answers:

- ***userdel -r bsmith**
- userdel bsmith
- ***userdel bsmith;rm -rf /home/bsmith**
- userdel -h bsmith
- userdel -Z bsmith

Explanation:

The **userdel -r** command deletes a user's home directory and user account. The **userdel** command by itself does not delete a user's home directory and user account. Executing **rm -rf** on the user's home directory after executing **userdel** removes the home directory.

The **userdel -h** command displays the syntax and options for the **userdel** command.

The **userdel -Z** command removes an SELinux user assigned to the user's login from SELinux login mapping. However, it does not delete the user home directory.

q_linux_usr_cmd_lockout_01_secp8

In the /etc/shadow file, which character in the password field indicates that a standard user account is locked?

Answers:

- !
- !!
- exclamation point
- Exclamation Point
- Exclamation point
- double exclamation point
- Double Exclamation Point

Explanation:

! or *!!* in the password field of /etc/shadow indicates that the account is locked and cannot be used to log in. The /etc/shadow file holds passwords and password expiration information for user accounts.

$ preceding the password identifies the password as an encrypted entry. * indicates a system user account entry (which cannot be used to log in).

q_linux_usr_cmd_lockout_02_secp8

Which of the following utilities could you use to lock a user account? (Select two.)

Answers:

- ***passwd**
- ***usermod**
- useradd
- userdel
- ulimit

Explanation:

Use the following utilities to lock a user account:

- **passwd -l** disables (locks) an account. This command inserts *!!* before the password in the /etc/shadow file.
- **usermod -L** disables (locks) an account. This command inserts *!* before the password in the /etc/shadow file.

The **useradd** command creates new user accounts, and **userdel** deletes user accounts from the system.

The **ulimit** command is used to limit computer resources.

q_linux_usr_cmd_lockout_03_secp8

You suspect that the gshant user account is locked.

Enter the command you would use in a Linux shell to show the status of the user account.

Answers:

- passwd -S gshant
- cat /etc/shadow
- tail /etc/shadow
- more /etc/shadow
- less /etc/shadow

Explanation:

Use **passwd -S gshant** to display the status of the gshant user account.

- LK indicates that the user account is locked.
- PS indicates that the user account has a password.

Viewing the /etc/shadow file also displays whether the user account is disabled. The second field for each entry in the /etc/password file is the password field:

- *$* preceding the password identifies the password as an encrypted entry.
- *!* or *!!* indicates the account is locked and cannot be used to log in.
- * indicates a system account entry, which cannot be used to log in.

q_usradd1_01

What is Paul Denunzio's user ID?

Answers:

- 509
- ***510**
- 517

q_linux_sec_history_secp8

What is the effect of the following command?

chage -M 60 -W 10 jsmith

Answers:

- ***Sets the password for jsmith to expire after 60 days and gives a warning 10 days before expiration.**
- Sets the password for jsmith to expire after 10 days and gives a warning 60 days before expiration.
- Deletes the jsmith user account after 60 days and gives a warning 10 days before expiration.

- Forces jsmith to keep the password for 60 days before changing it while also giving a warning 10 days before expiration.
- Sets the password for jsmith to expire after 60 days and sets a minimum of 10 days before a user can change the password again.

Explanation:

Using **chage -M 60 -W 10 jsmith** sets the password for jsmith to expire after 60 days and gives a warning 10 days before expiration.

Using **chage** sets user passwords to expire. Be aware of the following options:

- **-M** sets the maximum number of days before the password expires.
- **-W** sets the number of days before the password expires that a warning message displays.
- **-m** sets the minimum number of days that must pass after a password change before a user can change the password again.

q_linux_sec_reuse_secp8

Which of the following **chage** option keeps a user from changing their password every two weeks?

Answers:

- ***-m 33**
- -M 33
- -W 33
- -a 33

Explanation:

Using **chage -m 33** forces a user to keep his or her password for 33 days. This sets the minimum number of days that must pass after a password change before a user can change the password again. Be aware of the other **chage** options:

- **-M** sets the maximum number of days before the password expires.
- **-W** sets the number of days before the password expires that a warning message displays.

The **chage -a** option is not a valid option.

q_linux_sec_root_secp8

Which account type in Linux can modify hard limits using the **ulimit** command?

Answers:

- Standard
- Administrator
- ***Root**
- User

Explanation:

Only the root user in Linux can modify hard limits using the **ulimit** command.

Standard and administrator are Windows user types.

Users can modify soft limits but not hard limits using the **ulimit** command.

q_linux_sec_ulimit_01_secp8

Which of the following commands would you use to view the current soft limits on a Linux machine?

Answers:

- ulimit -c
- ulimit -n
- ***ulimit -a**
- ulimit -u

Explanation:

The **ulimit -a** command displays the current limits. The default shows soft limits.

The **ulimit -c** command limits the size of a core dump file.

The **ulimit -n** command limits the maximum number of files that can be open.

The **ulimit -u** command limits the number of concurrent processes a user can run.

q_linux_sec_ulimit_02_secp8

You are a system administrator and you notice that a particular user's processes are consuming an unusually high amount of system resources, causing performance issues for other users.

You decide to use the **ulimit** command to limit the resources available to this user's processes.

Which of the following options would be the MOST effective solution and why?

Answers:

- Use the -n option to limit the maximum number of files that the user can open.
- Use the -u option to limit the number of concurrent processes the user can run.
- Use the -f option to limit the file size of files created using the shell session.
- ***Use the -t option to limit the amount of CPU time a process can use.**

Explanation:

Limiting the amount of CPU time a process can use would be the most effective solution in this case. This would prevent any single process run by the user from consuming too much CPU time and causing performance issues for other users.

Limiting the number of files that the user can open might not be effective if the user's processes are not file-intensive. This option would be more useful if the user was opening a large number of files and causing I/O issues.

Limiting the number of concurrent processes the user can run could be effective if the user is running a large number of processes at the same time. However, if the user is running a small number of resource-intensive processes, this option might not help.

Limiting the file size of files created using the shell session might not be effective if the user's processes are not creating large files. This option would be more useful if the user was creating large files and filling up disk space.

q_linux_sec_user_security_secp8

What should you keep in mind when considering user security in a Linux environment?

Answers:

- ***Users should be trained to use secure passwords.**
- Passwords should never expire.
- Administrators should give users unlimited access to resources.
- Users should be allowed to change their passwords anytime they want without any restrictions.

Explanation:

Users should be trained to use secure passwords is the correct answer. Secure passwords use numbers and letters and are more than seven characters in length. This makes it harder for unauthorized users to guess or crack the passwords.

Passwords should expire periodically but not too often. This is to ensure that even if a password is compromised, it won't be valid for a long time, reducing the risk of unauthorized access.

Administrators can limit the resources that the user can access. This is a principle of least privilege, where users are given only the access they need to perform their tasks. This reduces the risk of accidental or deliberate misuse of resources.

While users should be allowed to change their passwords, there should be a minimum number of days that must pass after a password has been changed before a user can change the password again. This prevents users from quickly cycling through their password history to return to a preferred (possibly weak or compromised) password.

4.7 Linux Groups

As you study this section, answer the following questions:

- Which usermod option changes the secondary group membership?
- Which command removes all secondary group memberships for specific user accounts?
- Which groupmod option changes the name of a group?

In this section, you will learn to:

- Manage Linux groups
- Rename and create groups
- Add users to a group
- Remove a user from a group

This section helps you prepare for the following certification exam objectives:

Exam	Objective
CompTIA Security+ SY0-701	4.6 Given a scenario, implement and maintain identity and access management.

Exam	Objective
	• Provisioning/de-provisioning user accounts
TestOut Security Pro	1.1 Manage identity 1.1.2 Manage Linux users and groups

4.7.1 Managing Linux Groups (Demo Video)

Transcript:

For this demonstration, we're going to spend some timeÂ talking about how to manage groups on a Linux system.Â We'll talk about how to add a group,Â modify a group, and remove a group.

Let's begin by adding a new group to the system.Â Let's say we want to add a new groupÂ to the system named Development.Â We do this using the groupadd command. Notice that I'mÂ currently logged in as the rmckay user.Â Standard users on the system aren't allowed to add other users or groups. You can only do that as a user with sudo privileges or as the root user. For this demo, we're going to use â€˜su â€“ root'. You'll be prompted for the root password. Click Enter.
Before we add a new group to the system, I need to pointÂ out that there are several default parameters that areÂ automatically assigned to a new group when it's created.Â These defaults are stored in the /etc/login.defs file. Let's type â€˜less /etc/login.defs' to take a look.
First of all, the group ID number that's automaticallyÂ assigned when the group is created is defined here.Â They'll begin at 1000 on this system, so theÂ first group created will have a group ID of 1000.Â The next one will be 1001, the next one 1002, and so on.Â Likewise, if we created a system group on theÂ system, the group ID numbering would begin at 201. Every group ID is unique to the group.
let's use 'groupadd' and then specifyÂ the name of the group, 'Development'.Â We'll check to see if our group was created by typing â€˜tail /etc/group'.Â The X here tells us that it's using the gshadow passwordÂ file, but we haven't assigned any passwords.Â Here's the group ID number that's beenÂ assigned to that group. But notice, over here,Â that there are no members of that group yet.
In order to add members to a group, you mustÂ modify the group, but the actual command you use willÂ vary based upon what distribution you're using.
We used a capitalÂ D in the name of our group when it should have been a lowercase d like the rest of the groups.Â Let's make it match by modifyingÂ the group name: 'groupmod -n'.Â Now we specify the new group name that we want to use,Â 'development', and then we specify the name of the existingÂ group that we want to modify, 'Development', and click Enter.Â Let's view the end of the group file with a â€˜tail /etc/group' command. We see that the group has been renamed with a lowercase d.Â We know that's the same group and notÂ a new one because the group ID number,Â which uniquely identifies that group, is the same number as before.
To add usersÂ to a group, you can use the usermod command. Instead of modifying the group and adding usersÂ to it, we're going to modify a userÂ and tell it that it's now a member of this group.Â Let's go ahead and view the man page for usermod by typing â€˜man usermod'.Â As we scroll down, we should see the -gÂ options, lowercase g and uppercase G.
The lowercase g option is used toÂ modify the user's primary group, the default group.Â Remember that every user account on the Linux systemÂ has one primary group associated with it, and only one.Â If you want to change the default group for a userÂ account, you use the lowercase g option.Â Also remember that a Linux user can be a member of manyÂ other groups as well; these are our supplementary groups.Â If we want to add a user as a member of a supplementaryÂ group, we can use the uppercase G option instead.
Here's a very important thing that you have toÂ remember (and it trips up a lot of new LinuxÂ administrators): if you specify the usermod commandÂ and use the uppercase G option followed by the name ofÂ a group, whatever you specify with the G option willÂ overwrite whatever group memberships that user already has.Â If I have a user that's a

member of three differentÂ groups already, and I use the uppercase G optionÂ with the usermod command and specify an additional groupÂ that I want to make the user a member of, what actuallyÂ happens is the existing group memberships are removed andÂ replaced with the one group membership that I specify.Â If you want to add an additional group membership andÂ not replace an existing group membership, you need toÂ use the uppercase G option along with the -a option.Â The -a option appends the new group to theÂ list of group memberships instead of replacing it.
Let's go ahead and add development as aÂ supplementary group to my rmckay user account.Â To do this, I type 'usermod -G' followed by theÂ name of the group that I want to add, 'development'.Â Then I specify '-a' to indicate that I don't want toÂ remove any other group memberships already in place--I just want to add this as a new group membership.Â And then the name of the user account thatÂ I want to add the membership to, 'rmckay'. If we type â€˜groups rmckay', we can tell that the rmckay user is a part of the development group and hasn't lost any previously added groups.
Up to this point, we've talked about how to add a newÂ group, and we've talked about how to modify a group.Â Let's end this demonstration by discussingÂ how to remove a group from the system.Â This is done using the groupdel command. All I have to do is type 'groupdel development'.Â If we tail the group file with a â€˜tail /etc/group' command, we seeÂ that the development group is gone.
That's it for this demonstration.Â In this demo, we talked about how toÂ manage Linux groups from the command line.Â We talked about how to add aÂ group with the groupadd command.Â We talked about how to modify a groupÂ with the groupmod and usermod commands.Â Then we ended this demonstration by talking aboutÂ how to remove a group with the groupdel command.

4.7.2 Linux Group Commands

This lesson covers the following topic:

- Linux group commands

Linux Group Commands

Use the following commands to manage group accounts and group membership:

Command	Function
groupadd	Creates a new group. The following options override the settings found in the /etc/login.defs file: • **g** defines the group ID (GID). • **p** defines the group password. • **- r** creates a system group.
groupmod	Modifies the existing group.
groupdel	Modifies the system account files by deleting all entries that refer to the specified group. The named group must exist. You cannot remove the primary group of any existing user. You must remove the user before you remove the group.
gpasswd	Changes a group password. • **groupname** prompts for a new password. • **- r** removes a group password.
newgrp	Is used to change the current group ID during a login session. If the optional - flag is given, the user's environment will be reinitialized as though the user had logged in. Otherwise, the current environment,

Command	Function
	including the working directory, remains unchanged. You can use this when working in a directory where all the files must have the same group ownership.
usermod	Modifies group membership for the user account. Be aware of the following options: • **g** assigns a user to a primary group. • **G** assigns a user to a secondary group (or groups). Follow the command with a comma-separated list of groups. • **aG** assigns a user to a secondary group (or groups) by appending the group to any group the user already belongs to. Follow the command with a comma-separated list of groups. • **- G** "" removes the user from all secondary group memberships. Do not include a space between the quotes.
groups	Display the primary and secondary group membership for the specified user account.

4.7.3 Rename and Create Groups (Simulation)

Scenario

Currently, all the salespeople in your company belong to a group called sales. The VP of sales wants two sales groups, a western sales division, and an eastern sales division.

In this lab, your task is to:

- Rename the sales group to **western_sales_division** .
- Create the **eastern_sales_division** group.
- Remove **aespinoza** as a member of the **western_sales_division** group.
- Assign **aespinoza** as a member of the **eastern_sales_division** group.
- When finished, view the **/etc/group** file or use the **groups** command to verify the changes.

Explanation

Complete this lab as follows:

1. Rename the sales group *western_sales_division* and create the *eastern_sales_division* group.
   a. From the Favorites bar, select **Terminal** .
   b. At the prompt, type **groupmod -n western_sales_division sales** and press **Enter** .
   c. Type **groupadd eastern_sales_division** and press **Enter** .
2. Modify the group membership as needed.
   - Type **usermod -G eastern_sales_division aespinoza** and press **Enter** .

     When you assign aespinoza to the *eastern_sales_division* group using the **usermod -G** option, the user account is removed from the *western_sales_division* group.
3. Use **cat /etc/group** or **groups aespinoza** to verify aespinoza's group membership.

4.7.4 Add Users to a Group (Simulation)

Scenario

Maggie Brown (mbrown) and Corey Flynn (cflynn) have recently been hired in the human resources department. You have already created their user accounts.

In this lab, your task is to:

- Add the **hr** group as a secondary group for the mbrown and cflynn user accounts.
- When finished, view the **/etc/group** file or use the **groups** command to verify the changes.

When the **-g** switch is used with the **usermod** command, it sets the primary group membership, not the secondary one.

Explanation

Complete this lab as follows:

1. Add users to the hr group.
    a. From the Favorites bar, select **Terminal** .
    b. At the prompt, type **usermod -G hr mbrown** and press **Enter** .
    c. Use **usermod -G hr cflynn** and press **Enter** .
2. Verify the group membership for the users added to each group.
    a. Use **groups mbrown** and press **Enter** .
    b. Use **groups cflynn** and press **Enter** .

4.7.5 Remove a User from a Group (Simulation)

Scenario

Corey Flynn (cflynn) currently belongs to several groups. Due to some recent restructuring, he no longer needs to be a member of the hr group.

To preserve existing group membership, use the **usermod -G** command to list all groups to which the user must belong. Do not include the primary group name in the list of groups.

In this lab, your task is to:

- Remove **cflynn** from the hr group.
- Preserve all other group memberships.
- View the **/etc/group** file or use the **groups** command to verify the changes.

Explanation

Complete this lab as follows:

1. View a list of all groups to which Cory Flynn belongs.
    a. From the Favorites bar, select **Terminal** .
    b. At the prompt, type **groups cflynn** and press **Enter** .
    Notice that cflynn currently belongs to the *mgmt1* , *hr* , and *it* secondary groups. The cflynn group is the user's primary group.
2. Change and verify Cory Flynn's group membership.
    a. Type **usermod -G mgmt1,it cflynn** and press **Enter** .

b. Type **groups cflynn** and press **Enter** .
Cory now only belongs to the *mgmt1* and *it* groups.

4.7.6 Practice Questions (Section Quiz)

q_linux_grps_cmds_add_secp8

You are the administrator for a small company, and you need to add a standard new group of users to the system. The group's name is **sales**.

Which command accomplishes this task?

Answers:

- addgroup sales
- groupadd -r sales
- ***groupadd sales**
- addgroup --system sales

Explanation:

Use the **groupadd** utility to add a group to the system. By default, the group is added with an incrementing number above those reserved for system accounts.

If you use the **-r** option, the account is added as a system account (with a reserved group id number). Because this is a group that is created for users, the **-r** option should not be used.

The **--system** option adds a system group. However, in this scenario, you need to create a normal user group, not a system group.

q_linux_grps_cmds_del_secp8

You have a group named **temp_sales** on your system. The group is no longer needed, so you should remove it.

Which of the following commands should you use?

Answers:

- ***groupdel temp_sales**
- groupmod -R temp_sales
- groupmod -n temp_sales
- newgroup -R temp_sales

Explanation:

Use **groupdel** to delete a group from a Linux system.

The **newgroup** command logs the user into a group with the group password, but this command does not contain a **-R** option. The **groupmod** command modifies the existing group.

Be aware of the following options:

- **-A** adds specified users to the group (SUSE distribution).
- **-R** removes specified users from the group (SUSE distribution).
- **-n** changes the name of a group.

q_linux_grps_cmds_groupadd_secp8

Which of the following commands creates a new group and defines the group password?

Answers:

- groupadd -g
- ***groupadd -p**
- groupadd -r
- groupadd -c

Explanation:

The **groupadd -p** command creates a new group while defining the group password.

The **groupadd -g** command creates a new group while defining the GUID.

The **groupadd -r** command creates a new system group.

The **groupadd -c** command is not a valid command.

q_linux_grps_cmds_groups_secp8

You want to see which primary and secondary groups the dredford user belongs to. Enter the command you would use to display group memberships for **dredford**.

Answers:

- groups dredford
- groups dredford

Explanation:

To display the primary and secondary group membership for a specified user account, use the **groups** command. In this case, you would enter:

groups dredford

q_linux_grps_cmds_login_secp8

Using the **groupadd -p** command overrides the settings found in which file?

Answers:

- /etc/logins.txt
- /root/logins.defs
- /usr/logins.txt

- ***/etc/login.defs**

Explanation:

Using the **groupadd** command with the **-p** option overrides the default settings found in the /etc/login.defs file. The file is not located in the **/root/** directory.

There is no **logins.txt** file in Linux.

q_linux_grps_cmds_newgrp_secp8

Which of the following commands is used to change the current group ID during a login session?

Answers:

- ***newgrp**
- usermod
- groups
- groupmod

Explanation:

The **newgrp** command is used to change the current group ID during a login session. If the optional - flag is given, the user's environment is reinitialized as though the user had logged in. Otherwise, the current environment (including the current working directory) remains unchanged. You can use this when working in a directory in which all the files must have the same group ownership.

The **usermod** command modifies group membership for a user account.

The **groups** command displays the primary and secondary group membership for the specified user account.

The **groupmod** command modifies the existing group.

q_linux_grps_cmds_pass_secp8

You have a group named Research on your system that needs a new password because a member of the group has left the company.

Which of the following commands should you use?

Answers:

- ***gpasswd Research**
- newpasswd Research
- gpasswd research
- groupmod -p Research

Explanation:

Use **gpasswd Research** to be prompted to enter a new password for the Research group.

Group names are case-sensitive, so **gpasswd research** won't change the password for the Research group.

The **groupmod** command does not have a switch that can be used to change passwords.

The **newpasswd** option is not a valid Linux command.

q_linux_grps_cmds_primary_secp8

You are attempting to delete the temp group but are unable to.

Which of the following is the MOST likely cause?

Answers:

- All users have already been deleted.
- Groups cannot be deleted.
- ***The primary group of an existing user cannot be deleted.**
- The secondary group of an existing user cannot be deleted.

Explanation:

You cannot remove the primary group of any existing user. You must remove the user before you remove the group.

Deleting all users would not prevent a group from being deleted.

Groups can be deleted using the **groupdel** command.

Secondary groups of a user can be deleted. This event would not prevent a group from bring deleted.

q_linux_grps_cmds_remove_secp8

Which of the following commands removes a user from all secondary group memberships?

Answers:

- usermod -g
- usermod -G
- ***usermod -G ""**
- usermod -aG

Explanation:

usermod - G "" removes the user from all secondary group memberships. Do not include a space between the quotes.

usermod -g assigns a user to a primary group.

usermod -G assigns a user to a secondary group.

usermod -aG assigns a user to a secondary group (or groups) by appending the group to any which the user already belongs to. Follow the command with a comma-separated list of groups.

q_linux_grps_cmds_usermod_secp8

Which of the following commands assigns a user to a primary group?

Answers:

- ***usermod -g**
- usermod -G
- groupadd -g
- groupadd - r

Explanation:

The **usermod -g** command assigns a user to a primary group.

The **usermod -G** command assigns a user to a secondary group.

The **groupadd -g** command creates a new group while defining the GUID.

The **groupadd -r** command creates a new system group.

4.8 Remote Access

As you study this section, answer the following questions:

- How does EAP differ from CHAP?
- How can remote access and tunneling be secured?
- What is the difference between RADIUS and TACACS+?

In this section, you will learn to:

- Configure a RADIUS solution

This section helps you prepare for the following certification exam objectives:

Exam	Objective

CompTIA Security+ SY0-701	3.2 Given a scenario, apply security principles to secure enterprise infrastructure.
	• Secure communication/access
	  ○ Virtual private network (VPN)
	  ○ Remote access
	  ○ Tunneling
	  ▪ Internet Protocol Security (IPSec)
	
	4.1 Given a scenario, apply common security techniques to computing resources.
	• Wireless security settings
	  ○ AAA/Remote Authentication Dial-In User Service (RADIUS)

Exam	Objective
TestOut Security Pro	2.2 Harden network devices • 2.2.3 Configure and access a virtual private network (VPN)

4.8.1 Remote Access (Lesson Video)

Transcript:

In this lesson we're going to talk about remote access. Remote access involves the infrastructure, protocols, and software that allow a host to join a local network from a physically remote location or to establish a session on a host over a network.

Remote access networking means the user's device does not make a direct cable or wireless connection to the network. The connection occurs over or through an intermediate network.
Historically, remote access used analog modems connecting over the telephone system, but these days, most remote access is implemented as a virtual private network , or VPN, running over an ISP's network.
This client-to-site VPN topology is the "telecommuter" model, allowing homeworkers and employees working in the field to connect to the corporate network. The VPN protocol establishes a secure tunnel to keep the contents private, even when the packets pass over ISPs' routers.
The VPN client host first connects to a VPN gateway using an internet connection. The VPN gateway then authenticates the user and creates a secure encrypted tunnel. The VPN client traffic is routed over the network and can access authorized services.
A VPN can also be deployed in a site-to-site model to connect two or more private networks. While remote access VPN connections are typically initiated by the client, a site-to-site VPN is configured to operate automatically. The gateways exchange security information using whichever protocol the VPN is based on. This establishes a trust relationship between the gateways and sets up a secure connection through which to tunnel data. Hosts at each site do not need to be configured with any information about the VPN. The routing infrastructure at each site determines whether to deliver traffic locally or send it over the VPN tunnel.
Remote desktop refers to a technology that allows users to access and control a computer or device remotely. It enables individuals to connect to another computer over a network, typically the internet, and operate it as if they were physically in front of it.
With a remote desktop, you can access files, programs, and resources on a remote computer without having to be physically present at that location. This technology benefits remote work, technical support, collaboration, and access to personal or work-related resources from anywhere.
A remote access VPN joins the user's PC or smartphone to a remote private network via a secure tunnel over a public network. Remote access can also be a means of connecting to a specific computer over a network. This type of remote access involves connecting to a terminal server on a host using software that transfers shell data only. The connection could be a client and terminal server on the same local network or across remote networks.
A graphical remote access tool sends screen and audio data from the remote host to the client. It transfers mouse and keyboard input from the client to the remote host. Microsoft's Remote Desktop Protocol (RDP) can access a physical machine on a one-to-one basis.
That's it for this lesson. In this lesson, we discussed remote access architecture and remote desktop and how they help widen the geographical reach of an individual or an organization without the need for travel.

4.8.2 Remote Access Facts

Remote access involves the infrastructure, protocols, and software that allow a host to join a local network from a physically remote location or to establish a session on a host over a network.

This lesson covers the following topics:

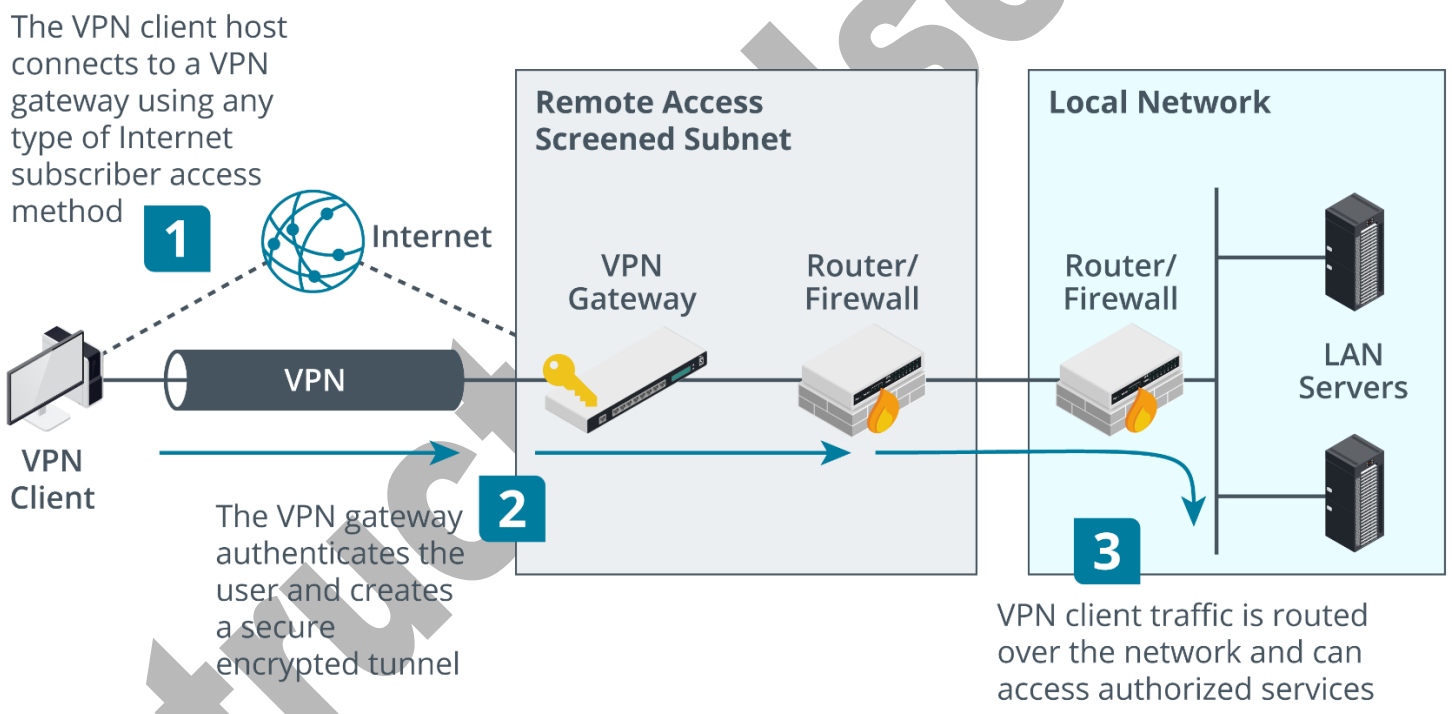
- Remote access architecture
- Remote desktop

Remote Access Architecture

Remote access networking means that the user's device does not make a direct cable or wireless connection to the network. The connection occurs over or through an intermediate network.

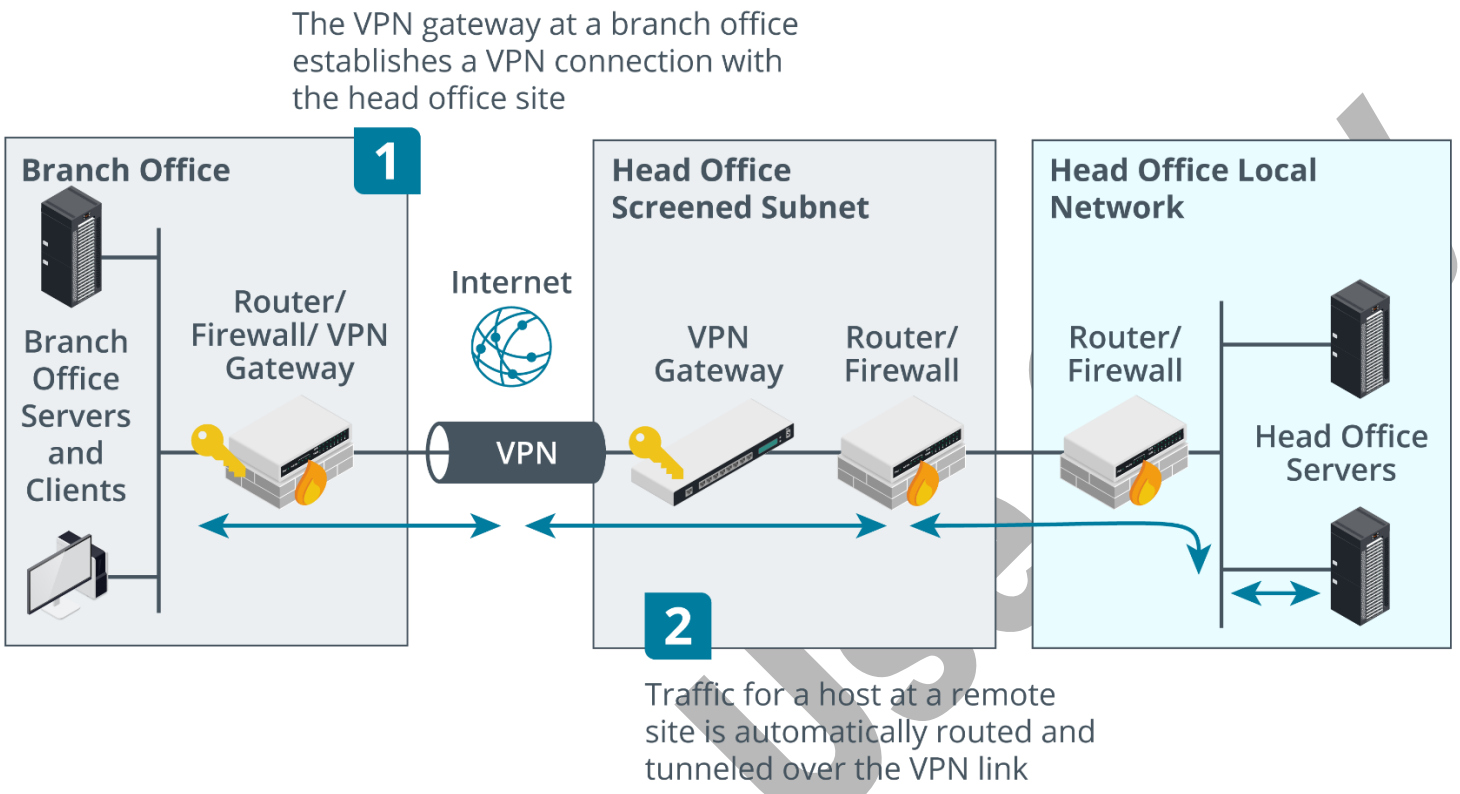
Historically, remote access used analog modems connecting over the telephone system. These days, most remote access is implemented as a virtual private network (VPN) , running over Internet Service Provider (ISP) networks.

With a remote access VPN, clients connect to a VPN gateway on the edge of the private network. This **client-to-site** VPN topology is the "telecommuter" model, allowing homeworkers and employees working in the field to connect to the corporate network. The VPN protocol establishes a secure tunnel to keep the contents private, even when the packets pass over ISPs' routers.



Remote access VPN. (Images © 123RF.com.)

A VPN can also be deployed in a **site-to-site** model to connect two or more private networks. Whereas remote access VPN connections are typically initiated by the client, a site-to-site VPN is configured to operate automatically. The gateways exchange security information using whichever protocol the VPN is based on. This establishes a trust relationship between the gateways and sets up a secure connection through which to tunnel data. Hosts at each site do not need to be configured with any information about the VPN. The routing infrastructure at each site determines whether to deliver traffic locally or send it over the VPN tunnel.



Site-to-site VPN. (Images © 123RF.com.)

A third topology is a **host-to-host tunnel** . This is a means of securing traffic between two computers where the private network is not trusted.

Several VPN protocols have been used over the years. Legacy protocols, such as the Point-to-Point Tunneling Protocol (PPTP), have been deprecated because they do not offer adequate security. Transport Layer Security (TLS) and Internet Protocol Security (IPsec) are now the preferred options for configuring VPN access.

Remote Desktop

A remote access VPN joins the user's PC or smartphone to a remote private network via a secure tunnel over a public network. Remote access can also be a means of connecting to a specific computer over a network. This type of remote access involves connecting to a terminal server on a host using software that transfers shell data only. The connection could be a client and terminal server on the same local network or across remote networks.

A graphical remote access tool sends screen and audio data from the remote host to the client and transfers mouse and keyboard input from the client to the remote host. Microsoft's Remote Desktop Protocol (RDP) can be used to access a physical machine on a one-to-one basis.

Alternatively, a site can operate a remote desktop gateway that facilitates access to virtual desktops or individual apps running on the network servers. RDP connections are encrypted by default. There are several popular alternatives to Remote Desktops. Most support remote access to platforms other than Windows (macOS and iOS, Linux, Chrome OS, and Android, for instance). Examples include TeamViewer (teamviewer.com/en) and Virtual Network Computing (VNC) , which is implemented by several different providers (notably realvnc.com/en).

In the past, these remote desktop products required a dedicated client app. Remote desktop access can now just use a web browser client. The canvas element introduced in HTML5 allows a browser to draw and update a desktop with relatively little lag. It can also handle audio. This is referred to as an HTML5 VPN or as a clientless remote desktop gateway (guacamole.apache.org). This solution uses a protocol called WebSocket, which enables bidirectional messages to be sent between the server and client without requiring the overhead of separate HTTP requests.

4.8.3 Configuring a RADIUS Solution (Demo Video)

Transcript:

Now, let's take a look at creating RADIUS clients. I'm going to go into my Network Policy Server management console. You can see up here that we have a list of RADIUS Clients and Remote RADIUS Servers. Whoever's talking to RADIUS needs to be configured as a RADIUS client. The only exception is if RADIUS is installed on the same server as Remote Access, which is actually the case in my environment. In that case, I don't need to configure Routing and Remote Access as a RADIUS client because it's on the same server.

When you install the Network Policy and Access server role, it changes what you see in Routing and Remote Access. Let's go into the Properties of my server here and to Security. Before I installed NPS, I had some drop-down combo boxes here that said, "Do you want to use Windows authentication or RADIUS authentication?" Now that I've installed NPS, I have to use it to configure authentication and accounting providers.
The most I can do here is change my authentication method. Installing NPS changes the interface for Routing and Remote Access. Let's say I had something else that was going to talk to NPS, a wireless router or wireless switch, a wired switch, or some other server that's running Routing and Remote Access, and it wants to talk to this NPS. I'd need to define them as a RADIUS client. I can define RADIUS client templates or right-click here and do a New RADIUS client. I can base this RADIUS client on an existing template. In that case, it will just fill out the information for me, or I can put in the information manually.
Then, I need to provide a Shared secret. This will be put in at both the RADIUS client and here at NPS, where I define the RADIUS client. It's just a phrase used to encrypt the connection. I can base it on templates or manually type in the Shared secret. No matter what, I have to define the RADIUS client for it to talk to NPS.
After this, you need to go to the RADIUS client itself—the switch, the other router, the other server, whatever's the RADIUS client—and tell it to talk to NPS on this server. How you do that depends on what's using this NPS for authentication, authorization, and accounting. It's always two steps: defining the RADIUS client on NPS and then, at the RADIUS client, defining RADIUS and pointing it to the NPS server.
There are several authentication methods using certificates for NPS that will need to be set up in order to have a secure authentication method, such as MS-CHAP V2, MS-CHAP, or CHAP.
That's it for this demo. In this demo, we went over the basics of configuring a RADIUS client and looked at how RADIUS affects routing and remote access.

4.8.4 RADIUS and TACACS+ Facts

This lesson covers the following topics:

- AAA server
- RADIUS
- TACACS+

AAA Server

An AAA server handles user requests for access to computer resources. A remote access server typically controls client access to remote systems. Clients might be restricted to accessing resources only on the remote access server, or they might be allowed to access resources on other hosts on the private network. Two standard AAA server solutions include RADIUS and TACACS+.

Remote access policies identify authorized users and other required connection parameters. In a small implementation, you typically define user accounts and remote access policies on the remote access server. With this configuration, you must define user accounts and policies on each remote access server. For larger deployments with multiple remote access servers, you can centralize the administration of remote access policies using an AAA server.

The remote access server receives connection requests from remote clients. It forwards them to the AAA server for approval or denial. The policies you define on the AAA server apply to all clients connected to all remote access servers.

RADIUS

Microsoft servers use RADIUS for centralized remote access administration. When using RADIUS, be aware that RADIUS:

- Combines authentication, authorization, and accounting. All three must be implemented through the RADIUS system.
- Allows for the separation of accounting to different servers. However, authentication and authorization remain combined on a single server.
- Supports PPP, CHAP, and PAP.
- Uses a challenge-response method for authentication.
- Does not transmit passwords in cleartext between the RADIUS client and the RADIUS server.
- A shared secret is used between the RADIUS server and the RADIUS client.
- The password is hashed, and the hash is added before it is transmitted.
- Encrypts only the password using MD5.
- Uses UDP ports 1812 and 1813 and can be vulnerable to buffer overflow attacks.
- Often uses vendor-specific extensions. RADIUS solutions from different vendors might not be compatible.

For example, a NAS device (RADIUS client) is configured with the IP address of the RADIUS server and a shared secret. This allows the client to authenticate to the server. Remember that the client is the access device (switch, access point, or VPN gateway), not the user's PC or laptop. A generic RADIUS authentication workflow proceeds as follows:

- The user's device (the supplicant) connects to the NAS appliance, such as an access point, switch, or remote access server.
- The NAS prompts the user for their authentication credentials. RADIUS supports PAP, CHAP, and EAP. Most implementations now use EAP, as PAP and CHAP are not secure. If EAP credentials are required, the NAS enables the supplicant to transmit EAP over LAN (EAPoL) data but not any other type of network traffic.
- The supplicant submits the credentials as EAPoL data. The RADIUS client uses this information to create an Access-Request RADIUS packet, encrypted using the shared secret. It sends the Access-Request to the AAA server using UDP on port 1812 (by default).
- The AAA server decrypts the Access-Request using the shared secret. If the Access-Request cannot be decrypted (because the shared secret is not correctly configured, for instance), the server does not respond.
- With EAP, Access-Challenge and Access-Request packets will be exchanged as the authentication method is set up and the credentials verified. The NAS acts as a pass-thru, taking RADIUS messages from the server and encapsulating them as EAPoL to transmit to the supplicant.
- At the end of this exchange, if the supplicant is authenticated, the AAA server responds with an Access-Accept packet; otherwise, an Access-Reject packet is returned.

Optionally, the NAS can use RADIUS for accounting (logging). Accounting uses port 1813. The accounting server can be different from the authentication server.

TACACS+

TACACS+ was originally developed by Cisco for centralized remote access administration. TACACS+:

- Provides three protocols, one each for authentication, authorization, and accounting. This allows each service to be provided by a different server.
- Uses TCP port 49.
- Encrypts the entire packet contents, not just authentication packets. The client-server dialogs are also encrypted.
- Supports more protocol suites than RADIUS.
- Requires remote access servers to become TACACS+ clients to the backend TACACS+ server, like a RADIUS solution.

TACACS was initially developed in 1984 by BBN Technologies. The protocol standard, TACACS+, was developed by Cisco Systems but is supported by many vendors, such as BlueCat Networks, IBM, Netgear, and more.

TACACS and Extended Terminal Access Controller Access-Control System (XTACACS) are older protocols developed before TACACS+. While they sound similar, they are different and less secure protocols.

4.8.5 Practice Questions (Section Quiz)

q_remote_acc_client_to_site_secp8

A company is planning to implement a remote access architecture to allow its employees to work from home.

The company has a central office where all its servers and applications are located. The employees need to access these resources securely from their home computers.

Which remote access architecture would be the most suitable for this scenario?

Answers:

- Site-to-site VPN topology
- Host-to-host tunnel topology
- ***Client-to-site VPN technology**
- Transport Layer Security (TLS)

Explanation:

Client-to-site VPN technology is the correct answer. Client-to-site VPN technology allows individual users to securely connect to a private network from a remote location. It establishes a secure tunnel between the user's device (the client) and the network's gateway (the site). This enables users to access resources, applications, and services within the private network as if they were physically present at the site. Client-to-site VPNs are commonly used for remote work.

A site-to-site VPN topology is used to connect two or more geographically separate networks over a public network such as the internet. This is typically used by businesses with multiple branch offices or organizations that must securely connect with external partners, not individual users.

A host-to-host tunnel topology is used for secure communication between specific hosts or endpoints. This type of VPN is typically used for secure file transfers, remote access to specific systems, or for establishing secure communication channels between devices in different locations. It is not suitable for connecting individual users to a central network.

While TLS is a protocol that provides privacy and data integrity between two communicating applications, it is not a remote access architecture. TLS is used within many VPN technologies for encryption and integrity checks, but it does not provide the VPN functionality itself.

q_remote_acc_host_to_host_secp8

A tech company is developing a new software product. The development team is distributed across different locations and needs to securely access and work on specific systems located in the company's main office.

The team members need to establish secure communication channels between their individual devices and the specific systems in the office.

Which remote access architecture would be the most suitable for this scenario?

Answers:

- Client-to-site VPN technology
- Site-to-site VPN topology
- ***Host-to-host tunnel topology**
- Virtual network computing (VNC)

Explanation:

Host-to-host tunnel topology is the correct answer. In a host-to-host tunnel topology, individual devices establish a secure tunnel between each other over a public network. This type of VPN is typically used for secure communication between specific hosts or endpoints, which is exactly what the team members need in this scenario.

Client-to-site VPN technology is typically used when individual users need to securely connect to a private network from a remote location. In this scenario, the team members need to establish secure communication channels with specific systems, not the entire network.

A site-to-site VPN topology is used to connect two or more geographically separate networks over a public network such as the Internet. This is typically used by businesses with multiple branch offices or organizations that must securely connect with external partners, not for secure communication between specific hosts or endpoints.

While VNC allows for remote control of another computer, it does not inherently provide the secure, encrypted tunnels needed for this scenario. VNC is a type of remote desktop software, not a remote access architecture. It would allow the team members to control the specific systems, but it would not provide the secure communication channels they need.

q_remote_acc_rdp_secp8

A multinational corporation wants to enable its IT support team to provide remote assistance to employees across various locations. The support team needs to be able to take control of the employees' computers to troubleshoot and resolve issues.

The corporation primarily uses Windows-based systems.

Which technology would be the MOST suitable for this purpose?

Answers:

- Simple Network Management Protocol (SNMP)
- ***Remote Desktop Protocol (RDP)**
- Transport Layer Security (TLS)
- Remote Authentication Dial-in User Service (RADIUS)

Explanation:

Remote Desktop Protocol (RDP) is the correct answer. RDP is a proprietary protocol developed by Microsoft that allows a user to connect to another computer over a network connection in a graphical interface. This makes it ideal for IT support teams to remotely control and troubleshoot issues on employees' computers.

SNMP is an application protocol for monitoring and managing network devices. While it can provide valuable information about network devices, it does not allow for remote control of a user's desktop.

TLS is a cryptographic protocol that provides secure communication over a computer network. While it is used to secure communications, it does not provide the functionality to remotely control a user's desktop.

RADIUS is a networking protocol that provides centralized authentication, authorization, and accounting (AAA) management for users who connect and use a network service. While it is used for managing remote and wireless authentication infrastructures, it does not allow for remote control of a user's desktop.

q_remote_acc_remote_secp8

You often travel away from the office. While traveling, you would like to use your laptop computer to connect directly to a server in your office and access files. You want the connection to be as secure as possible.

Which type of connection do you need?

Answers:

- ***Remote access**
- Internet
- Virtual private network
- Intranet

Explanation:

Use a remote access connection to connect directly to a server at a remote location.

You could use a virtual private network (VPN) connection through the internet to connect to the server security. However, the connection would involve connecting first to the internet through a local ISP and then establishing a VPN connection to the server. While the VPN connection through the internet is secure, it is not as secure as a direct remote connection to the server.

An intranet is an internal network that only internal users can access.

q_remote_acc_tls_secp8

Which of the following protocols is primarily used for secure remote access to a network by creating an encrypted tunnel over the internet?

Answers:

- Simple Network Management Protocol (SNMP)
- Remote Desktop Protocol (RDP)
- ***Transport Layer Security (TLS)**
- Hypertext Transfer Protocol (HTTP)

Explanation:

Transport Layer Security (TLS) is the correct answer. TLS is a protocol that provides privacy and data integrity between two communicating applications. It's used to create an encrypted tunnel for secure remote access to a network over the internet.

SNMP is primarily used for managing and monitoring network devices, not for secure remote access to a network.

Remote Desktop Protocol (RDP) is primarily used for remote desktop access, allowing a user to control another computer over a network connection. While it does provide a form of remote access, it is not primarily used for creating an encrypted tunnel for secure network access.

Hypertext Transfer Protocol (HTTP) is used for transmitting hypertext over the internet, not for secure remote access to a network. HTTP does not provide the necessary encryption for secure remote access.

q_remote_acc_vpn_sol_secp8

A global pharmaceutical company's IT team needs a secure solution for remote employees to access internal company resources from home.

The solution must require user authentication, encapsulate and encrypt all traffic between the user and the internal network, and establish a secure tunnel.

Which solution should the team choose?

Answers:

- ***Virtual Private Network (VPN)**
- Secure Shell (SSH)
- Simple Network Management Protocol (SNMP)
- Remote Desktop Protocol (RDP)

Explanation:

A VPN creates a secure private connection between the remote user's device and the company's internal network that requires authentication and uses a network tunnel.

SSH offers secure, encrypted command-line access and file transfer but does not encapsulate all traffic and does not create a network tunnel.

SNMP is a device management protocol for IP networks, not for creating a secure connection for a remote user.

RDP allows a user to remotely access and control another machine but does not encrypt all traffic or create a network tunnel. RDP focuses on direct connection to a single machine.

q_radius_tacacs_aaa_secp8

What is the primary function of an AAA server in a network?

Answers:

- To provide email services to all users
- ***To handle user requests for access to computer resources**
- To store all data and files in the network
- To provide internet connectivity to all devices in the network

Explanation:

To handle user requests for access to computer resources is the correct answer. An AAA server (authentication, authorization, and accounting) handles user requests for access to computer resources. It typically controls client access to remote systems and can centralize the administration of remote access policies.

An AAA server does not provide email services. Email services are typically provided by an email server.

An AAA server does not store all data and files in the network. This is typically the role of a file server or a database server.

An AAA server does not provide internet connectivity. This is typically the role of a router or a modem.

q_radius_tacacs_radius_secp8

RADIUS is primarily used for what purpose?

Answers:

- Managing access to a network over a VPN
- ***Authenticating remote clients before access to the network is granted**
- Managing RAID fault-tolerant drive configurations
- Controlling entry-gate access using proximity sensors

Explanation:

Remote Authentication Dial-In User Service (RADIUS) is primarily used for authenticating remote clients before access to a network is granted.

RADIUS is based on RFC 2865 and maintains client profiles in a centralized database.

RADIUS offloads the authentication burden for dial-in users from the normal authentication of local network clients.

For environments with a large number of dial-in clients, RADIUS provides improved security, easier administration, improved logging, and alleviated performance impact on LAN security systems.

q_radius_tacacs_tac_char_01_secp8

Which of the following are characteristics of TACACS+? (Select two.)

Answers:

- ***Uses TCP**
- Uses UDP
- ***Allows three different servers (one each for authentication, authorization, and accounting)**
- Allows two different servers (one for authentication and authorization and another for accounting)
- Can be vulnerable to buffer overflow attacks

Explanation:

TACACS+ was originally developed by Cisco for centralized remote access administration. TACACS+:

- Provides three protocols (one each for authentication, authorization, and accounting). This allows each service to be provided by a different server.
- Uses TCP.
- Encrypts the entire packet contents.
- Supports more protocol suites than RADIUS.

RADIUS is used by Microsoft servers for centralized remote access administration. RADIUS:

- Combines authentication and authorization using policies to grant access.
- Uses UDP.
- Encrypts only the password.
- Often uses vendor-specific extensions. RADIUS solutions from different vendors might not be compatible.
- Uses UDP ports 1812 and 1813 and can be vulnerable to buffer overflow attacks.

q_radius_tacacs_tac_char_02_secp8

Which of the following is a characteristic of TACACS+?

Answers:

- ***Encrypts the entire packet, not just authentication packets**
- Requires that authentication and authorization are combined in a single server
- Uses UDP ports 1812 and 1813
- Supports only TCP/IP

Explanation:

TACACS+ was originally developed by Cisco for centralized remote access administration. TACACS+:

- Provides three protocols (one each for authentication, authorization, and accounting). This allows each service to be provided by a different server.
- Uses TCP port 49.
- Encrypts the entire packet contents, not just authentication packets.
- Supports more protocol suites than RADIUS.

RADIUS is used by Microsoft servers for centralized remote access administration. RADIUS:

- Combines authentication and authorization using policies to grant access.
- Allows the separation of accounting to different servers. However, authentication and authorization remain combined on a single server.
- Uses UDP ports 1812 and 1813.
- Uses a challenge/response method for authentication. RADIUS encrypts only the password using MD5.

q_radius_tacacs_tac_dif_secp8

Which of the following are differences between RADIUS and TACACS+?

Answers:

- RADIUS uses TCP; TACACS+ uses UDP.
- RADIUS encrypts the entire packet contents; TACACS+ only encrypts the password.

- ***RADIUS combines authentication and authorization into a single function; TACACS+ allows these services to be split between different servers.**
- RADIUS supports more protocols than TACACS+.

Explanation:

TACACS+ provides three protocols (one each for authentication, authorization, and accounting). This allows each service to be provided by a different server. In addition, TACACS+:

- Uses TCP
- Encrypts the entire packet contents
- Supports more protocol suites than RADIUS

q_radius_tacacs_tac_port_secp8

Which of the following ports are used with TACACS?

Answers:

- 22
- ***49**
- 50 and 51
- 1812 and 1813
- 3389

Explanation:

Terminal Access Controller Access Control System (TACACS) uses port 49 for TCP and UDP.

Port 22 is used by Secure Shell (SSH).

Protocol numbers 50 and 51 are used by IPsec.

Ports 1812 and 1813 are used by Remote Authentication Dial-In User Service (RADIUS).

Port 3389 is used by Remote Desktop Protocol (RDP).

4.9 Network Authentication

As you study this section, answer the following questions:

- In the challenge/response process, what information is exchanged over the network during logon?
- What is included in a digital certificate?
- What is PKI?
- Which tool can manage authentication credentials on Windows hosts?

The key terms for this section include:

Term	Definition

Authentication	Authentication is the process of validating user credentials that prove user identity.

This section helps you prepare for the following certification exam objectives:

Exam	Objective

CompTIA Security+ SY0-701	3.8 Given a scenario, implement authentication and authorization solutions.
	• Authentication
	  ○ EAP
	  ○ 802.1X
	  ○ Single sign-on (SSO)
	  ○ Security Assertions Markup Language (SAML)
	  ○ OAuth
	  ○ OpenID
	  ○ Kerberos

TestOut Security Pro	1.0 Identity Management and Authentication 1.2 Harden Authentication

4.9.1 Network Authentication Protocols (Lesson Video)

Transcript:

Network authentication is the process of validating user credentials that prove user identity. Authentication is typically the first step in connecting to a network. Following successful authentication, access controls can be implemented to allow or deny access to network resources. In this lesson, we'll discuss single sign-on authentication, Federation, and OAuth—all methods used for network authentication.

Single Sign-on (SSO) is an authentication method that enables users to use the same login credentials to access multiple applications. A user only needs to authenticate once and then receive authorizations on compatible application servers without entering credentials again. Kerberos is a single sign-on network authentication and authorization protocol used on many networks, as implemented by Microsoft's Active Directory (AD) service.
Kerberos was named after the three-headed guard dog of Hades (Cerberus) because it consists of three parts: the client, the network resource, and a key distribution center. The clients request services from application servers, which rely on an intermediary—a key distribution center (KDC)—to vouch for their identity. Two services comprise a KDC: the Authentication Service and the Ticket Granting Service. Kerberos can authenticate human users and application services. These are collectively referred to as principals.
Using authentication to a Windows domain as an example:
The principal sends the authentication service (AS) a request for a Ticket Granting Ticket, or TGT. This is composed by encrypting the date and time on the local computer with the user's password hash as the key. The password hash itself isn't transmitted over the network. Although we refer to passwords for simplicity, the system can use other authenticators, such as smart card login.
The AS checks that the user account is present, that it can decode the request by matching the user's password hash with the one in the Active Directory database, and that the request hasn't expired. If the request is valid, the AS responds with a TGT and a TGS session key. A TGT contains information about the client (name and IP address) plus a time stamp and validity period. This is encrypted using the KDC's secret key. A TGS session key communicates between the client and the Ticket Granting Service (TGS). This is encrypted using a hash of the user's password.

The TGT is an example of a logical token. All the TGT does is identify who you are and confirm that you've been authenticated—it doesn't provide you with access to any domain resources. Presuming the user entered the correct password, the client can decrypt the Ticket Granting Service (TGS) session key but not the TGT. This establishes that the client and KDC know the same shared secret and that the client can't interfere with the TGT.

To access resources within the domain, the principal requests a service ticket—a token that grants access to a target application server. This process of granting service tickets is handled by the TGS. The principal sends the TGS a copy of its TGT, the name of the application server it wishes to access, and an authenticator consisting of a time-stamped client ID encrypted using the TGS session key. This confirms that the request is genuine. It also checks that the ticket hasn't expired or been used before.

The TGS service responds with a service session key and a service ticket. The service session key is used between the client and the application server. This is encrypted with the TGS session key. A service ticket contains information about the principal, such as a time stamp, system IP address, SID, the SIDs of groups to which it belongs, and the service session key. This is encrypted using the application server's secret key.

The principal forwards the service ticket, which it can't decrypt, to the application server and adds another time-stamped authenticator, which is encrypted using the service session key. The application server decrypts the service ticket to obtain the service session key using its secret key, confirming that the principal has sent it an untampered message. It then decrypts the authenticator using the service session key.

Now let's look at Federation. Federation is the notion that a network needs to be accessible to more than just a well-defined group of employees. A company might need to open parts of its network to partners, suppliers, and customers. The company can manage its employee accounts easily enough. Managing accounts for each supplier or customer internally may be more difficult. Federation means the company trusts accounts created and managed by a different network. As another example, in the consumer world, a user might want to use both Google Workspace and Twitter. Suppose Google and Twitter establish a federated network for authentication and authorization. In that case, users can log on to Twitter using their Google credentials or vice versa.

These interoperable federation protocols use claims-based identity. While the technical implementation and terminology differ, the overall model is like that of Kerberos SSO: The service provider, SP, and Identity Provider, or IdP, have a pre-established trust relationship. The user starts a session with the service provider.

The service provider redirects the principal to an IdP to authenticate. The user authenticates to the IdP. The IdP issues a claims token to the user. The user then presents the claims token to the SP. The SP validates that the IdP has signed the claim because of its trust relationship with the IdP. The service provider can now connect the authenticated principal to its accounts database to determine its permissions and other attributes.

Lastly, let's talk about Open Authorization. Open Authorization, often called OAuth, allows an application to authorize access without exposing the user's password. In a simplified sense, it's like a valet key for the web. It will enable a user's account information to be used by third-party services, such as Facebook or Twitter, without exposing their password. This means the user's sensitive details are handled only by the service they trust (i.e., their 'identity provider') and not the third-party applications requesting access.

OAuth is designed to facilitate the sharing of information or resources within a user profile between sites. The user creates a password-protected account at an identity provider. The user can link that identity to an OAuth consumer site without giving the password to the consumer site. Users can grant an OAuth client authorization to access some of their accounts. A client in this context is an app or consumer site. OAuth operates through a series of handshakes between three key players: the client—the application wanting access; the server—the application that holds the user's data; and the resource owner—the user.

Here's a simplified step-by-step of the process: The client requests authorization from the resource owner to access their data, which is held on the server. If the resource owner gives permission, the client receives an authorization grant. The client exchanges the authorization grant for an access token by requesting the server.

The server validates the authorization grant, and if it's correct, it issues an access token to the client. The client uses this access token to request the resource owner's data from the server. The server serves the client the requested data if the access token is valid. It's important to note that at no point does the client learn the resource owner's credentials, maintaining security and privacy of sensitive user information.

That's it for this lesson. In this lesson, we discussed network authentication. We talked about single sign-on authentication and authorization, federation, and open authorization. We also reviewed the step-by-step process for each of the network authentication methods.

4.9.2 Network Authentication Facts

This lesson covers the following topics:

- Network authentication overview
- Single sign-on authentication
- Single sign-on authorization
- Federation
- Open authorization

Network Authentication Overview

Authentication is the process of validating user credentials that prove user identity. Authentication is typically the first step in connecting to a network. Following successful authentication, access controls can be implemented to allow or deny access to network resources.

A simple form of authentication sends a username and password to an authentication server. If the password is sent in cleartext, the authentication credentials can be intercepted and used to impersonate an authorized user. One method of protecting login credentials is using a challenge/response mechanism (also called a three-way handshake). By doing so, both the authentication server and the authenticator are configured with a common shared secret. This shared secret is usually a password associated with a user account. The process is:

1. The authentication server sends a challenge string to the authenticator.
2. The authenticator uses the shared secret to hash the challenge string and returns the user account name and the hashed value to the authentication server.
3. The authentication server also uses its shared secret value to hash the challenge string. If the two hashed values match, the authentication server assumes the authenticator knows the shared secret.

Single Sign-on Authentication

A single sign-on (SSO) system allows users to authenticate once and then receive authorizations on compatible application servers without entering credentials again.

Kerberos is a single sign-on network authentication and authorization protocol used on many networks, as implemented by Microsoft's Active Directory (AD) service. Kerberos was named after the three-headed guard dog of Hades (Cerberus) because it consists of three parts. Clients request services from application servers, which rely on an intermediary—a key distribution center (KDC) —to vouch for their identity. Two services comprise a KDC: the Authentication Service and the Ticket Granting Service.

Kerberos can authenticate human users and application services. These are collectively referred to as principals. Using authentication to a Windows domain as an example, the first step in Kerberos SSO is to authenticate with a KDC server implemented as a domain controller.

- The principal sends the authentication service (AS) a request for a Ticket Granting Ticket (TGT). This is composed by encrypting the date and time on the local computer with the user's password hash as the key. The password hash itself is not transmitted over the network. Although we refer to passwords for simplicity, the system can use other authenticators, such as smart card login.
- The AS checks that the user account is present, that it can decode the request by matching the user's password hash with the one in the Active Directory database, and that the request has not expired. If the request is valid, the AS responds with the following data:
    - Ticket Granting Ticket (TGT) — contains information about the client (name and IP address) plus a time stamp and validity period. This is encrypted using the KDC's secret key.
    - TGS session key — communicates between the client and the Ticket Granting Service (TGS). This is encrypted using a hash of the user's password.

The TGT is an example of a logical token. All the TGT does is identify who you are and confirm that you have been authenticated—it does not provide you with access to any domain resources.

Single Sign-on Authorization

Presuming the user entered the correct password, the client can decrypt the Ticket Granting Service (TGS) session key but not the TGT. This establishes that the client and KDC know the same shared secret and that the client cannot interfere with the TGT.

- The principal requests a service ticket to access resources within the domain (a token that grants access to a target application server). This process of granting service tickets is handled by the TGS.
- The principal sends the TGS a copy of its TGT, the name of the application server it wishes to access, and an authenticator consisting of a time-stamped client ID encrypted using the TGS session key. The TGS should be able to decrypt both messages using the KDC's secret key for the first and the TGS session key for the second. This confirms that the request is genuine. It also checks that the ticket has not expired and has not been used before (replay attack).
- The TGS service responds with the following:
    - A Service session key — is used between the client and the application server. This is encrypted with the TGS session key.
    - A Service ticket — contains information about the principal, such as a time stamp, system IP address, Security Identifier (SID), the SIDs of groups to which it belongs, and the service session key. This is encrypted using the application server's secret key.
- The principal forwards the service ticket, which it cannot decrypt, to the application server and adds another time-stamped authenticator, which is encrypted using the service session key.
- The application server decrypts the service ticket to obtain the service session key using its secret key, confirming that the principal has sent it an untampered message. It then decrypts the authenticator using the service session key.
- Optionally, the application server responds to the principal with the time stamp used in the authenticator, which is encrypted using the service session key. The principal decrypts the time stamp, verifies that it matches the value already sent, and concludes that the application server is trustworthy. This means the server is authenticated to the principal (mutual authentication). This prevents an on-path attack, where a malicious user could intercept communications between the principal and server.
- The server now responds to access requests (assuming they conform to the server's access control list).

Federation

Federation is the notion that a network needs to be accessible to more than just a well-defined group of employees. A company might need to open parts of its network to partners, suppliers, and customers. The company can manage its employee accounts easily enough. Managing accounts for each supplier or customer internally may be more difficult. Federation means the company trusts accounts created and managed by a different network. As another example, in the consumer world, a user might want to use both Google Workspace and Twitter. Suppose Google and Twitter establish a federated network for authentication and authorization. In that case, users can log on to Twitter using their Google credentials or vice versa.

An on-premises network can use technologies such as LDAP and Kerberos, very often implemented as a Windows Active Directory network, because the administration of accounts and devices can be centralized. When implementing Federation, authentication and authorization design comes with more constraints and additional requirements to ensure interoperability between different platforms. Web applications might not support Kerberos, while third-party networks might not support direct Federation with Active Directory/LDAP. The design for these cloud networks likely requires using other standard protocols or frameworks for interoperability between web applications.

These interoperable federation protocols use claims-based identity. While the technical implementation and terminology are different, the overall model is similar to that of Kerberos SSO:

- The principal attempts to access a service provider (SP). The service provider redirects the principal to an identity provider (IdP) to authenticate.

- The principal authenticates with the identity provider and obtains a claim in the form of a token or document signed by the IdP.
- The principal presents the claim to the service provider. The SP can validate that the IdP has signed the claim because of its trust relationship with the IdP.
- The service provider can now connect the authenticated principal to its accounts database to determine its permissions and other attributes. It may be able to query attributes of the user account profile held by the IdP if the principal has authorized this type of access.

A federated network or cloud needs specific protocols and technologies to implement user identity assertions and transmit claims between the principal, the relying party, and the identity provider. Security Assertion Markup Language (SAML) is one such solution. SAML assertions (claims) are written in eXtensible Markup Language (XML). Communications are established using HTTP/HTTPS and the Simple Object Access Protocol (SOAP). The secure tokens are signed using the XML signature specification. Using a digital signature allows the relying party to trust the identity provider.

Open Authorization

Many public clouds use application programming interfaces (APIs) based on Representational State Transfer (REST) rather than SOAP. These are called RESTful APIs. Where SOAP is a tightly specified protocol, REST is a looser architectural framework. This allows the service provider more choice over implementation elements. Compared to SOAP and SAML, there is better support for mobile apps.

Authentication and authorization for a RESTful API are often implemented using the Open Authorization (OAuth) protocol. OAuth is designed to facilitate the sharing of information (resources) within a user profile between sites. The user creates a password-protected account at an identity provider (IdP). The user can link that identity to an OAuth consumer site without giving the password to the consumer site. A user (resource owner) can grant an OAuth client authorization to access some part of their account. A client in this context is an app or consumer site.

The user account is hosted by one or more resource servers. A resource server is called an API server because it hosts the functions that allow OAuth clients (consumer sites and mobile apps) to access user attributes. An authorization server processes authorization requests. A single authorization server can manage multiple resource servers; equally, the resource and authorization server could be the same server instance.

The client app or service must be registered with the authorization server. As part of this process, the client registers a redirect URL, which is the endpoint that will process authorization tokens. Registration also provides the client with an ID and a secret. The ID can be publicly exposed, but the client and the authorization server must keep the secret confidential. When the client application requests authorization, the user approves the authorization server to grant the request using an appropriate method. OAuth supports several grant types—or flows—for use in different contexts, such as server to server or mobile app to server. Depending on the flow type, the client will end up with an access token validated by the authorization server. The client presents the access token to the resource server, which then accepts the request for the resource if the token is valid.

4.9.3 LDAP Authentication (Lesson Video)

Transcript:

In this lesson, we'll discuss the Lightweight Directory Access Protocol authentication, or LDAP.

LDAP is an open-source protocol used to communicate with network directories. It is a lightweight, fast protocol that runs over TCP/IP. That makes it ideal for internet-based access requests. Because LDAP is an open protocol, most applications can access a desired server regardless of the directory service being used to manage authentication. LDAP traffic is in cleartext by default, but LDAP can run using SSL or some type of transport-level security.
So, how exactly does LDAP work? Let's say we have a client who is trying to access network resources. The network's server has been configured with Active Directory.

Active Directory includes a database with details about authorized network user's information including usernames, passwords, and groups. It also stores information about various network resources including the level of access each user has to that resource.
To be compliant with the LDAP protocol, data must be stored using a standard method. For example, each database entry must be an object with specific attributes. This structure helps to ensure that a directory can be easily accessed and the desired information can be found.
To obtain access to the network, Active Directory and the client must speak the same language. This is where LDAP comes in. The client sends a request with required credentials to Active Directory. When Active Directory receives the request and the credentials, it compares them the information to the database. If the information matches, the request is authorized. The client is then connected to the appropriate network resources.
You must set up LDAP to authenticate credentials against the information stored in directory services. A bind method sets the authentication state for an LDAP session. You can use one of two options to perform the authentication.
Simple Authentication uses name and password authentication, unauthenticated authentication, or anonymous authentication. Most of the time, a name and a password create the bind request that's sent to the server.
Simple Authentication and Security Layer authentication, or SASL, uses a different authentication service such as Kerberos to bind to the LDAP server. The LDAP server then uses this authentication service. This method provides additional security because the authentication method is separated from the application protocols.
As you can see, while directory services provide security specific to your network, LDAP provides a method for communication with remote clients. LDAP and directory services work hand in hand to keep your network secure.
That's it for this lesson. In this video, we discussed the Lightweight Directory Access Protocol. We discussed what it is and how it works. We also covered the two authentication methods, simple authentication and SASL authentication.

4.9.4 LDAP Authentication Facts

This lesson covers the following topics:

- Directory services
- Securing directory services

Directory Services

A directory service stores information about users, computers, security groups/roles, and services. Each object in the directory has several attributes. The directory schema describes the types of attributes, what information they contain, and whether they are required or optional. For products from different vendors to be interoperable, most directory services are based on the Lightweight Directory Access Protocol (LDAP), which was developed from a standard called X.500.

Within an X.500-like directory, a distinguished name (DN):

- Is a collection of attributes that define a unique identifier for any given resource.
- Is made up of attribute-value pairs, separated by commas. The most specific attribute is listed first, and successive attributes become progressively broader. This most specific attribute is the relative distinguished name, as it uniquely identifies the object within the context of successive (parent) attribute values.

Some of the attributes commonly used include common name (CN), organizational unit (OU), organization (O), country (C), and domain component (DC).

CN=WIDGETWEB, OU=Marketing, O=Widget, C=UK, DC=widget, DC=foo

Securing Directory Services

A network directory lists the subjects (principally users, computers, and services), objects (such as directories and files) available on the network, and subjects' permissions over objects. A directory facilitates authentication and authorization and must be maintained as a highly secure service. Most directory services are based on the Lightweight Directory Access

Protocol (LDAP), running over port 389. The basic protocol provides no security, and all transmissions are plaintext, making it vulnerable to sniffing and on-path attacks. Authentication (referred to as binding to the server) can be implemented in the following ways:

- No Authentication — means anonymous access is granted to the directory.
- Simple Bind — means the client must supply its distinguished name (DN) and password, passed as plaintext.
- Simple Authentication and Security Layer (SASL) — means the client and server negotiate using a supported authentication mechanism, such as Kerberos. The STARTTLS command can require encryption (sealing) and message integrity (signing). This is the preferred mechanism for Microsoft's Active Directory (AD) implementation of LDAP.
- LDAP Secure (LDAPS) — means the server is installed with a digital certificate, which it uses to set up a secure tunnel for the user credential exchange. LDAPS uses port 636.

If secure access is required, anonymous and simple authentication methods should be disabled on the server.

Generally, two access levels must be granted on the directory: read-only access (query) and read/write access (update). This is implemented using an access control policy, but the precise mechanism is vendor-specific and not specified by the LDAP standards documentation.

Unless hosting a public service, the LDAP directory server should only be accessible from the private network. This means that the LDAP port should be blocked by a firewall from accessing the public interface. If there is integration with other services over the internet, ideally, only authorized IPs should be permitted.

4.9.5 Practice Questions (Section Quiz)

q_netauth_federation_secp8

A manufacturing company recently bought out another similar company. They need to link each company's directory systems together to access their resources without merging the two.

How can they link the two directory systems together?

Answers:

- Site-to-site VPN
- Migration
- ***Federation**
- Location-based restrictions

Explanation:

Federation directories allow two different subsets of accounts to work together for permissions and access.

A site-to-site virtual private network (VPN) is similar to the VPN that employees use. However, they connect two or more location-separated corporate resources.

Over time, merging companies will migrate employee accounts from one directory to another. However, they do not need to work with each other seamlessly.

Location-based restrictions are not as efficient and do not provide for linking directories together.

q_netauth_kerberos_secp8

When using Kerberos authentication, which of the following terms is used to describe the token that verifies the user's identity to the target system?

Answers:

- Coupon
- Voucher
- ***Ticket**
- Hashkey

Explanation:

The tokens used in Kerberos authentication are known as *tickets*. Tickets perform a number of functions, including notifying the network service of the user who has been granted access and authenticating the identity of that person when he or she attempts to use the network service.

The terms *coupon* and *voucher* are not associated with Kerberos or any other commonly implemented network authentication system.

The term *hashkey* is sometimes used to describe a value that has been derived from some piece of data when that value is then used to access a service. This term is not associated with Kerberos.

q_netauth_mutual_secp8

What is mutual authentication?

Answers:

- ***A process by which each party in an online communication verifies the identity of the other party.**
- The use of two or more authentication factors.
- Deploying CHAP and EAP on remote access connections.
- Using a certificate authority (CA) to issue certificates.

Explanation:

Mutual authentication is the process by which each party in an online communication verifies the identity of the other party. Mutual authentication is most common in VPN links, SSL connections, and e-commerce transactions. In each of these situations, both parties in the communication want to ensure that they know with whom they are interacting.

The use of two or more authentication factors is called two-factor authentication. Challenge Handshake Authentication Protocol (CHAP) and Extensible Authentication Protocol (EAP) are authentication protocols.

Communicating hosts might use certificates issued by a trusted CA in performing mutual authentication. However, using the CA is not, in itself, a definition of mutual authentication.

q_netauth_oauth_01_secp8

In a company, different departments actively access various cloud-based applications and services to perform their tasks efficiently. The company's security team has concerns about the growing complexity and risks of managing user credentials across multiple platforms.

To address this concern proactively, the team implements a modern authentication solution that actively provides single sign-on (SSO) capabilities, ensuring enhanced user convenience and security.

In this scenario, which technology should the organization proactively employ for federation and enabling SSO capabilities effectively across the diverse range of cloud-based applications?

Answers:

- ***Open Authorization (OAuth)**
- Role-based access control (RBAC)
- Lightweight Directory Access Protocol (LDAP)
- Public key infrastructure (PKI)

Explanation:

In this scenario, the organization uses Open Authorization (OAuth) for federation, allowing secure authorization and delegation of user access to third-party applications without exposing user credentials.

While role-based access control (RBAC) is a valuable access control model, it is not directly related to federation and SSO capabilities across multiple cloud-based applications.

Although used to access and manage directory information, Lightweight Directory Access Protocol (LDAP) is not the technology used for federation and SSO in the given scenario.

Public key infrastructure (PKI) is a cryptographic system that uses public and private keys for secure communication and authentication. While it plays a role in security, there are other technologies for federation and SSO in this context.

q_netauth_oauth_02_secp8

In a large healthcare organization, multiple departments handle sensitive patient data. Each department requires access to different applications and systems to carry out its tasks efficiently.

However, granting broad access rights through long-lived authentication tokens poses security risks.

What solution should the IT department implement while adhering to the principle of least privilege and securing sensitive patient data?

Answers:

- ***Open Authorization (OAuth)**
- JSON web token (JWT)
- Multi-factor authentication (MFA)
- Kerberos

Explanation:

OAuth (Open Authorization) is a widely used authentication framework that enables secure authorization between different services and aligns with the principle of least privilege.

JWT (JSON web token) is a compact, URL-safe means of representing claims between two parties. Unlike OAuth, which focuses on authorization delegation, JWT is more about transmitting claims.

MFA (Multi-factor authentication) enhances security by requiring users to provide multiple forms of verification before accessing systems. While MFA is valuable, it doesn't inherently address the issue of granting time-limited access to different departments.

Kerberos is a network authentication protocol that relies on tickets for granting access. While it offers secure authentication, it doesn't directly address the issue of temporal or ephemeral access rights.

q_netauth_oauth_03_secp8

A company wants to set up single sign-on (SSO) without passing credentials through to each piece of software and cloud service.

Which protocol would meet this requirement?

Answers:

- Kerberos
- FIDO
- VPN
- ***OAuth**

Explanation:

The Open Authorization (OAuth) protocol is a system that facilitates sharing of information (resources) within a user profile between sites. The user can link that identity to an OAuth consumer site without giving the password to the consumer site.

The preferred system for network authentication in a Windows environment is Kerberos which replaces the legacy system NT LAN Manager (NTLM) authentication.

Passwordless authentication means that the whole system no longer processes knowledge-based factors. The Fast IDentity Online 2 (FIDO2) with WebAuthn specifications provides a framework for passwordless authentication.

A virtual private network (VPN) is how an individual can access corporate resources outside the corporate infrastructure.

q_netauth_oauth_04_secp8

You are a security analyst at a large corporation. Your company has recently implemented an Open Authorization (OAuth) system to allow third-party applications to access company resources.

One day, you notice an unusual amount of data being transferred from your company's servers to an unknown third-party application.

What should be your first course of action?

Answers:

- Ignore the situation as the OAuth system is designed to allow third-party applications to access company resources.
- Immediately block all data transfers to the third-party application without further investigation.
- ***Investigate the third-party application to understand why it is accessing a large amount of data.**
- Report the situation to the company's legal department without conducting any further investigation.

Explanation:

Investigating the third-party application is the correct answer. This action will help you understand why the OAuth system is accessing a large amount of data. This could reveal whether the data transfer is legitimate or if there is a potential security breach.

While OAuth is designed to allow third-party applications to access company resources, an unusual amount of data transfer could indicate a potential security breach or misuse of access privileges.

While it might be necessary to block data transfers eventually, doing so immediately without further investigation could disrupt legitimate business operations and does not address the root cause of the issue.

While it might be necessary to involve the legal department eventually, doing so without conducting any further investigation does not address the immediate potential security risk.

q_netauth_saml_01_secp8

In a multinational corporation, employees across various departments regularly access many cloud-based applications to fulfill their tasks efficiently. The company's security team is grappling with managing user credentials securely and efficiently across these diverse platforms.

They are actively looking to improve user authentication and streamline access to these applications while ensuring robust security measures are in place.

In this scenario, what technology should the company implement to enable single sign-on (SSO) capabilities and ensure secure authentication across its diverse cloud-based applications?

Answers:

- ***Security Assertion Markup Language (SAML)**
- Lightweight Directory Access Protocol (LDAP)
- Remote Authentication Dial-In User Service (RADIUS)
- Virtual private network (VPN)

Explanation:

Security Assertion Markup Language (SAML) enables secure SSO across various applications by exchanging authentication and authorization data between parties through an extensible markup language (XML)-based protocol.

Lightweight Directory Access Protocol (LDAP) queries and modifies directory services but does not work with SSO or cloud-based application authentication.

Remote Authentication Dial-In User Service (RADIUS) is primarily utilized for authenticating users in network access scenarios and does not cater to SSO across cloud-based applications.

A virtual private network (VPN) establishes secure connections between remote networks, but there are no links to enabling SSO or cloud-based application authentication.

q_netauth_saml_02_secp8

A real estate investment firm wants to implement single sign-on (SSO) for its dozens of services and software. The firm found a vendor to implement that request using the eXtensible Markup Language (XML) standard.

What solution does this vendor use for SSO?

Answers:

- ***SAML**
- VPN
- LDAP
- LSASS

Explanation:

Security Assertion Markup Language (SAML) allows for federating a network or cloud system. SAML assertions and claims between the principal, the relying party, and the identity provider use eXtensible Markup Language as their structure.

A virtual private network (VPN) allows individuals to access corporate resources outside the corporate infrastructure. Employees cannot access a file share without a VPN if they are not at their office.

LDAP is a protocol that makes it possible for applications to query user information rapidly. It is not an XML solution.

LSASS is a process in Microsoft Windows operating systems that is responsible for enforcing the security policy on a system.

q_netauth_shared_secret_secp8

In a three-way handshake during network authentication, what is the term for the common value that both the authentication server and the authenticator are configured with?

Answers:

- ***Shared secret**
- Public key
- Private key
- Digital signature

Explanation:

Shared secret is the correct answer. In a three-way handshake, both the authentication server and the authenticator are configured with a common value known as a shared secret. This is usually a password associated with a user account.

In public key cryptography, the public key is used to encrypt data and it's publicly available. It's not the common value used in a three-way handshake.

In public key cryptography, the private key is kept secret by the owner and is used to decrypt data. It's not the common value used in a three-way handshake.

A digital signature is a mathematical scheme for verifying the authenticity of digital messages or documents. It's not the common value used in a three-way handshake.

q_netauth_tgs_secp8

In a Kerberos authentication system, how does the Ticket Granting Service (TGS) contribute to the single sign-on (SSO) process?

Answers:

- The TGS generates the initial Ticket Granting Ticket (TGT) for the client.
- The TGS validates the client's password and username.
- ***The TGS issues service tickets to clients for accessing specific services.**
- The TGS encrypts all data transferred between the client and the application server.

Explanation:

The TGS issues service tickets to clients after they have been authenticated. These service tickets allow clients to access specific services without having to re-authenticate.

The initial Ticket Granting Ticket (TGT) is generated by the authentication service (AS), not the TGS.

The validation of the client's password and username is also done by the authentication service (AS), not the TGS.

While the TGS does play a role in the encryption process by providing session keys, it does not encrypt all data transferred between the client and the application server. The encryption of data transferred between the client and the server is done using session keys, which are provided by the TGS but the actual encryption is done at the client and server ends.

q_ldap_access_levels_secp8

Which of the following are the access levels that are generally granted on the directory in LDAP? (Select two.)

Answers:

- ***Read-only access**
- ***Read/write access**
- Full control access
- Execute access
- Delete access

Explanation:

The following are the access levels generally granted on the directory in LDAP:

- Read-only access (query) - This level of access allows users to view and query the data in the directory but not modify it. It's essential for users who need to retrieve information but should not change it.
- Read/write access (update) - This level of access allows users to both view and modify the data in the directory. It's necessary for users who need to update or change the information in the directory.

While full control access is used in some systems to denote a user having all possible permissions, it's not a standard access level in LDAP. In LDAP, permissions are typically more granular and are defined by the specific access (read, write, etc.) a user has to specific objects or attributes.

Execute access is typically used in file system permissions to denote the ability to run a file as a program. In the context of LDAP, which is a directory service, this concept doesn't apply.

While the ability to delete objects is a type of permission that can be granted in LDAP, it's not one of the two primary access levels that must be granted. The primary levels are read-only and read/write.

q_ldap_dn_secp8

What BEST describes a distinguished name (DN) in the context of a directory service?

Answers:

- ***A unique identifier for any given resource in a directory, made up of attribute-value pairs.**
- A security protocol used to protect directory services.
- A type of directory service developed from the X.500 standard.
- A method of authentication in the Lightweight Directory Access Protocol (LDAP).

Explanation:

A distinguished name (DN) is a unique identifier for any given resource in a directory, made up of attribute-value pairs. The DN provides a way to locate a specific object in the directory.

A DN is not a security protocol. It is a unique identifier used in directory services.

While DN is used in directory services, it is not a type of directory service itself. X.500 is a standard from which LDAP, a type of directory service, was developed.

A DN is not a method of authentication. It is a unique identifier used in directory services. Authentication methods in LDAP include No Authentication, Simple Bind, Simple Authentication and Security Layer (SASL), and LDAP Secure (LDAPS).

q_ldap_firewall_secp8

In the context of LDAP security, why would an organization choose to block the LDAP port with a firewall?

Answers:

- ***To prevent unauthorized access to the directory from the public network.**
- To disable the LDAP service entirely.
- To force the use of LDAPS instead of LDAP.
- To prevent the directory from storing any new data.
- To disable all network communication.

Explanation:

The correct answer is to prevent unauthorized access to the directory from the public network. Blocking the LDAP port with a firewall can help prevent unauthorized access from the public network. This is a common security measure to protect sensitive directory information.

To disable the LDAP service entirely is incorrect. Blocking the LDAP port with a firewall does not disable the LDAP service. It simply restricts access to the service from certain networks.

While LDAPS (LDAP Secure) does use a different port than standard LDAP, blocking the LDAP port does not force the use of LDAPS. The use of LDAPS must be configured separately.

Blocking the LDAP port with a firewall does not prevent the directory from storing new data. It only restricts network access to the LDAP service, not all network communication. Other services and protocols can still communicate over the network.

q_ldap_ou_secp8

Which of the following is a commonly used attribute in Lightweight Directory Access Protocol (LDAP)?

Answers:

- ***Organizational Unit (OU)**
- Internet Protocol (IP)
- Firewall
- Public network

Explanation:

Organizational Unit (OU) is the correct answer. In LDAP, an Organizational Unit (OU) is a type of attribute used to organize objects within a directory. It can represent a logical or physical entity in the organization, such as a department or a location.

While IP addresses are crucial for network communication, they are not considered an attribute in LDAP. LDAP attributes are characteristics of directory objects, such as users or devices, not network protocols.

A firewall is a network security device that monitors and filters incoming and outgoing network traffic based on an organization's previously established security policies. It is not an attribute in LDAP.

A public network refers to a network that is accessible to the general public. It is not an attribute in LDAP. LDAP attributes are used to define characteristics of objects within the directory, not types of networks.

q_ldap_sasl_secp8

An educational institution's systems administrator is responsible for securing the LDAP directory service for the organization's computing resources.

Which authentication method should the systems administrator implement to ensure secure access?

Answers:

- No authentication
- Simple Bind
- ***Simple Authentication and Security Layer (SASL)**
- LDAP Secure (LDAPS)

Explanation:

SASL allows the client and server to negotiate a supported authentication mechanism and provides the option to use the command STARTTLS for encryption and message integrity. This feature is a secure way to access the Lightweight Directory Access Protocol (LDAP) directory.

Enabling anonymous access (no authentication) to the directory is not secure, exposing it to potential misuse and unauthorized access.

In a simple bind, the client either binds anonymously, that is, with an empty bind DN, or by providing a DN and a password. This is not a secure method for LDAP.

LDAP Secure (LDAPS) uses TLS/SSL as a transmission protocol. However, this is not as secure as using SASL.

q_ldap_secure_secp8

The IT administrator for a large university uses an LDAP directory service to manage user access to various computing resources.

To ensure the directory's security, which of the following measures should the administrator implement?

Answers:

- Allow anonymous access to the directory for easy user onboarding.
- Use the basic LDAP protocol without any additional security mechanisms.
- Implement Simple Bind with plaintext transmission of distinguished name and password.
- ***Set up LDAP Secure (LDAPS) with a digital certificate on port 636 for secure user credential exchange.**

Explanation:

Setting up LDAP Secure (LDAPS) with a digital certificate on port 636 for secure user credential exchange encrypts data and ensures the protection of user credentials during transmission by providing a secure tunnel.

Exposing sensitive data and creating potential security risks results from anonymous access to the directory, making it not recommended for secure environments.

Using the basic LDAP protocol without any additional security mechanisms does not provide the extra security needed in this scenario.

Implementing Simple Bind with plaintext transmission of distinguished name and password does not provide the level of security needed in this scenario.

5.0 Network Architecture

5.1 Enterprise Network Architecture

As you study this section, answer the following questions:

- What is network architecture?
- What is Internet Protocol?
- What needs should be considered when setting up security zones?
- What security protocols help reduce the attack surface?

The key terms for this section include:

Term	Definition
Network architecture	The selection and placement of media, devices, protocols/services, and data assets.
Network infrastructure	The media, appliances, and addressing/forwarding protocols that support basic connectivity.
Internet Protocol (IP)	Provides the addressing mechanism for logical networks and subnets.
Attack surface	All the points at which a threat actor could gain access to hosts and services.

This section helps you prepare for the following certification exam objectives:

Exam	Objective

CompTIA Security+ SY0-701	3.1 Compare and contrast security implications of different architecture models.
	• Architecture and infrastructure concepts
	  ○ Cloud
	  ▪ Responsibility matrix
	  ▪ Hybrid considerations

5.1.1 Enterprise Network Architecture (Lesson Video)

Transcript:

In this lesson, we'll explore the fundamentals of network design, from architecture decisions to device placement. Let's get started!

Network architecture is like the blueprint of a network. It involves choosing and arranging components such as media, devices, protocols or services, and data assets. Within this framework, we have network infrastructure, which consists of the physical elements like cables, appliances, and addressing and forwarding protocols that enable basic connectivity. Network applications are the services running on this infrastructure to support business activities like processing invoices or sending emails. Data assets are the information generated as a result of these activities.
The goal of secure network infrastructure and application architecture is to support secure business workflows, where security means ensuring confidentiality, integrity, and availability.
Let's take the example of provisioning email services to understand the architecture decisions involved.
Access control ensures that client devices access the network through a secure channel with authentication and authorization. Unauthorized users and devices must be denied access.
The email mailbox server stores data assets securely and must be accessible only to authorized clients. It should also be fault-tolerant and highly available.

The mail transfer server, responsible for connecting with untrusted internet hosts, requires careful control to manage communications between the untrusted network and trusted LAN. Any data or software leaving or entering the network must be subject to policy-based controls.
This type of business flow will involve systems with different security requirements. Placing the client, the mailbox, and the mail transfer server all within the same segment will introduce many vulnerabilities. Understanding and controlling how data flows between these network segments is a key part of secure and effective network architecture design.
Now, let's dive into network infrastructure using the OSI model, a framework for understanding network layers.
At the physical layer (Layer 1), we find various transmission media, from cables to wireless signals, which are the links connecting network nodes. Now, nodes come in two types:
host nodes, which initiate data transfers (like servers or clients), and intermediary nodes that forward traffic around the network.
Networks can vary in scope, from local area networks (LANs) for a single site to wide area networks (WANs) that span metropolitan, country-wide, or global scopes.
Each network node must have a unique address, and this addressing function occurs at different layers and scopes. Various network appliances and protocols handle forwarding and addressing functions, such as switches, routers, transport protocols, application protocols, and DNS servers.
When designing a network, several factors come into play. Costs, including upfront investments and ongoing maintenance, need to be considered. Compute resources affect processing time for various workloads. Scalability and ease of deployment help manage changes in workload. Availability and resilience minimize downtime and recovery time in case of failures. Facility power usage capabilities and patch availability are also vital considerations, along with the option of risk transference through service-level agreements. These factors together shape the architecture of your network.
The selection of effective controls for network infrastructure is the process of choosing the type and placement of security appliances and software. The aim is to enforce segmentation, apply access controls, and monitor traffic for policy violations.
Guided by the principle of defense in depth, diverse controls are placed at different OSI layers to enhance security. You have three options: preventive controls at network borders, detective controls within the perimeter, and a combination of preventive, detective, and corrective controls on hosts. For instance, a firewall at the network border enforces access rules, while a sensor behind it relays traffic to an intrusion detection system for monitoring. Access control lists on internal routers enforce rules for traffic between zones, and load balancers can help mitigate denial-of-service attacks.
Endpoint protection software on hosts adds another layer of security, implementing host firewalls, anti-virus, intrusion detection, and data loss prevention.
Lastly, attributes determine the precise way in which a device can be placed within the network topology.
Controls can be active or passive. Active controls require configuration and data exchange, while passive controls operate silently.
Deployment can be inline, becoming part of the network path, or as taps or monitors, capturing traffic transparently. The router/firewall is an active control as client devices must be configured to use it for internet access. The TAP and mirror ports are passive controls. They're completely transparent to the server and client hosts.
That's it for this lesson. In this lesson, we discussed network architecture and how it's the blueprint of your network design. We then talked about how the network infrastructure fits within the architecture framework. We used the OSI model to help us understand how different components of the infrastructure fit together. Next, we reviewed the many architecture considerations that factor into your network design. We also discussed device placement and security controls. We finished this lesson by looking at device attributes that determine how a security control affects device placement.

5.1.2 Enterprise Network Architecture Facts

This lesson covers the following topics:

- Network architecture
- Network infrastructure and OSI model
- Architecture considerations
- Device placement and security controls
- Device attributes

Network Architecture

Network architecture means the selection and placement of media, devices, protocols/services, and data assets:

- Network infrastructure is the media, appliances, and addressing/forwarding protocols that support basic connectivity.
- Network applications are the services that run on the infrastructure to support business activities, such as processing invoices or sending email.
- Data assets are the information that is created, stored, and transferred as a result of business activity.

Secure network infrastructure and application architecture are put there to support secure business workflows. A workflow is a series of tasks that a business needs to perform, such as accepting customer orders from a web store. Remember that security means the attributes of confidentiality, integrity, and availability.

Analyzing the systems involved in provisioning email can illustrate the sorts of architecture decisions that need to be made:

- Access—the client device must access the network via a physical channel and obtain a logical address. The user must be authenticated and authorized to use the email application. The corollary is that unauthorized users and devices must be denied access.
- Email mailbox server—the mailbox stores data assets and must only be accessed by authorized clients, and conversely, must be fully available and fault tolerant to support the genuine user. The email service must run with a minimum number of dependencies over network infrastructure that is resilient to faults.
- Mail transfer server—this must connect with untrusted internet hosts, so communications between the untrusted network and trusted LAN must be carefully controlled. Any data or software leaving or entering the network must be subject to policy-based controls.

This type of business flow will involve systems with different security requirements. Placing the client, the mailbox, and the mail transfer server all within the same segment will introduce many vulnerabilities. Understanding and controlling how data flows between these network segments is a key part of secure and effective network architecture design.

Network Infrastructure and the OSI Model

It is helpful to use a layer model to analyze network infrastructure and services. The Open Systems Interconnection (OSI) model is a widely quoted example of how to define layers of network functions.

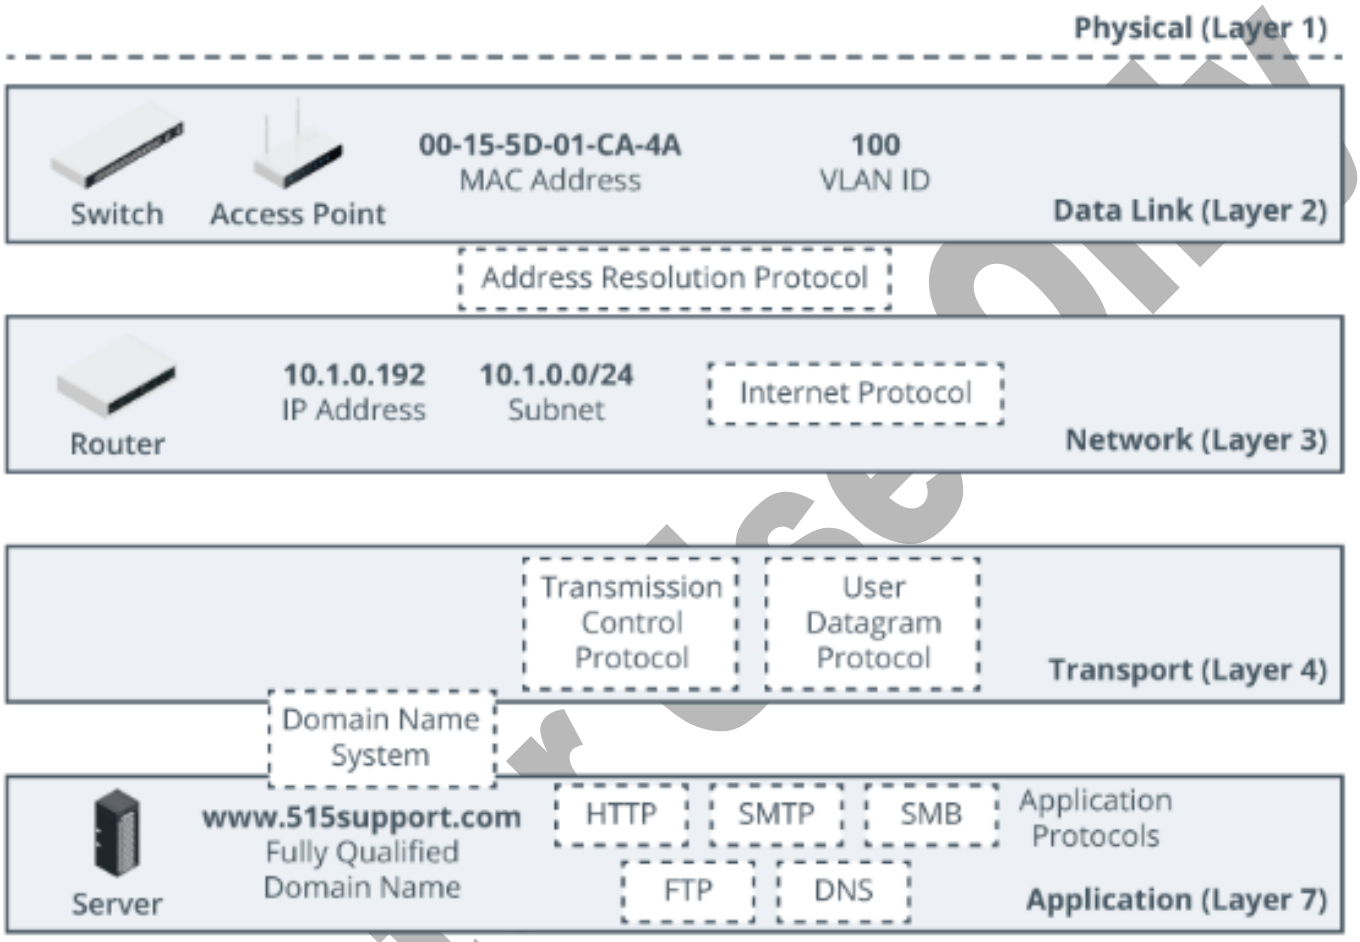
A network is comprised of nodes and links. At the physical (PHY) layer, or layer 1 in the OSI model, links are implemented as twisted-pair cables transmitting electrical signals, fiber optic cables carrying infrared light signals, or as wireless devices transmitting radio waves.

There are two types of nodes. A host node is one that initiates data transfers. Hosts are usually either servers or clients. An intermediary node forwards traffic around the network. This forwarding occurs at different layers and with different scopes. A network scope of a single site is referred to as a local area network (LAN). Networks that span metropolitan, country-wide, or global scopes are called wide area networks (WANs).

Each network node must be identifiable via a unique address. This addressing function also takes place at different layers with different scopes.
Forwarding and addressing functions are handled by the following network appliances and protocols:

- A switch forwards frames between nodes in a cabled network. The network adapter in each host is connected to a switch port via a cable. Switches work at layer 2 of the OSI model. Most LANs use networks based on the Ethernet standard. An Ethernet switch makes forwarding decisions based on the hardware or media access control (MAC) address of attached hosts. A MAC address is a 48-bit value written in

hexadecimal notation, such as00-15-5D-01-CA-4A. This addressing works within the local network segment only. This is referred to as a broadcast domain.



Appliances, protocols, and addressing functions within the OSI network layer reference model. (Images © 123RF.com.)

- Wireless access points provide a bridge between a cabled network and wireless hosts, or stations. Access points work at layer 2 of the OSI model. Wireless devices also use MAC addressing at layer 2.
- Routers send packets around an internetwork, making forwarding decisions based on Internet Protocol (IP) addresses. Routers work at layer 3 of the OSI model. Each local segment will normally have a router connected to it. The router acts as a default gateway for hosts on the segment to use to send packets to other segments.
- Transport protocols allow clients to exchange data with application servers. The Transmission Control Protocol (TCP) establishes reliable connections, while the User Datagram Protocol (UDP) allows unreliable, connectionless transfers. Each application protocol is identified by a TCP or UDP port. This functionality is defined at layer 4 of the OSI model.
- Application protocols support client/server functionality for user-level services, such as web browsing, email, and file transfer. Application protocols work at layer 7 of the OSI model.
- Domain Name System (DNS) servers host name records and perform name resolution to allow applications and users to address hosts and services using fully qualified domain names (FQDNs) rather than IP addresses. DNS also works at layer 7 of the OSI model, but is an infrastructure service, rather than a user-level service, like web browsing.

The OSI model has three upper layers. In practical terms, distinguishing the functions of layers 5, 6, and 7 isn't that helpful, so just think of applications working at layer 7.

Architecture Considerations

When evaluating the use of a particular architecture and selecting effective controls, consider a number of factors:

- Costs—architecture changes, the acquisition and upgrade of appliances, and software require an up-front capital outlay, which can depreciate and lose value. There are also ongoing maintenance and support liabilities. The value of the investment in security architecture and controls can be calculated based on how much they reduce losses from incidents.
- Compute and responsiveness—minimize processing time for workloads. A workload is the processing effort required to complete a task, such as a web server responding to a client request. Each network device requires sufficient CPU, system memory, storage, and network bandwidth resources to ensure an acceptable response time for a given workload. Higher compute resources incur greater costs.
- Scalability and ease of deployment —minimize costs when workloads increase or decrease. If workloads decrease it can be difficult to recover capital costs. If workloads increase it can be difficult to deploy new nodes or upgrade existing nodes to maintain responsiveness. A scalable system is one that can quickly or automatically add or remove compute resources without incurring excessive costs.
- Availability—minimizes downtime or maximizes uptime. Downtime represents the loss of opportunity to do work, damaging the business's reputation, revenue, and profitability. Downtime can be due to planned maintenance or unplanned failures and security incidents.
- Resilience and ease of recovery —reduce the time to recover from a failure. For example, a system that recovers from a failure without manual intervention is more resilient than one that requires an administrator to restart it.
- Power—is a feature that ensures the facility can meet the energy demands of its devices and workloads. Power usage through higher compute resources increases costs. Ensuring that the building infrastructure minimizes power failures improves availability.
- Patch availability—ensures that firmware and software code is protected against exploits for known vulnerabilities. Conversely, the network owner cannot manage this process when they rely on a third party to maintain infrastructure or when a device or software product is no longer supported by its vendor.
- Risk transference—is a contract that uses a third party to manage the network infrastructure. A service-level agreement (SLA) can be defined with penalties if metrics for responsiveness, scalability, availability, and resilience are not maintained.

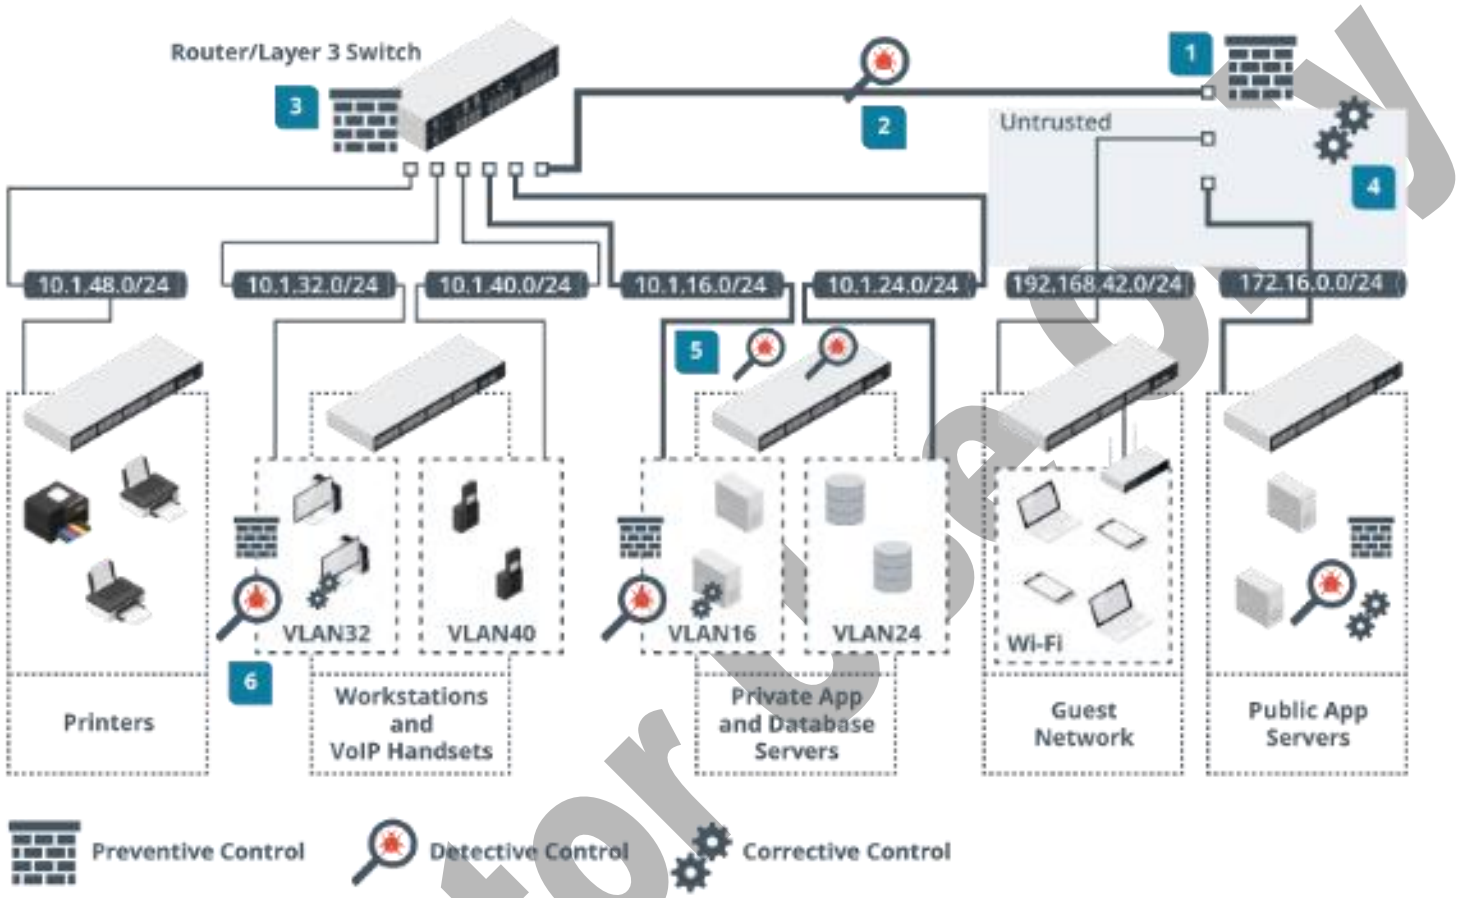
On-premises networks tend to have high capital costs and low scalability. For example, consider the difficulty of increasing bandwidth from 1 Gbps to 10 Gbps operation across the entire site. This would likely require the installation of new cable throughout the building. Recovery procedures can be complex if the site premises is affected by a large-scale disaster. This means that availability and resilience can be lower than alternative solutions such as cloud networking.

Device Placement and Security Controls

The selection of effective controls for network infrastructure is the process of choosing the type and placement of security appliances and software. The aim is to enforce segmentation, apply access controls, and monitor traffic for policy violations. The selection of effective controls is governed by the principle of defense in depth. Defense in depth means that security-critical zones are protected by diverse preventive, detective, and corrective controls operating at each layer of the OSI model. Defense in depth is ensured through careful selection of device placement within the network topology. There are three options:

- Preventive controls—are often placed at the border of a network segment or zone. Preventive controls such as firewalls enforce security policies on traffic entering and exiting the segment, ensuring confidentiality and integrity. A load balancer control ensures high availability for access to the zone.
- Detective controls—might be placed within the perimeter to monitor traffic exchanged between hosts within the segment. This provides alerting of malicious traffic that has evaded perimeter controls.

- Preventive, detective, and corrective controls —might be installed on hosts as a layer of endpoint protection in addition to the network infrastructure controls.



Placement of security controls to ensure diversity and defense in depth.

As an illustration, the diagram shows how different control types can be positioned within the network to ensure defense in depth:

- At the network border, a preventive control such as a firewall enforces access rules for ingress and egress traffic.
- A sensor placed inline behind the border firewall relays traffic to an intrusion detection system to implement detective control and identify malicious traffic that has evaded the firewall.
- Access control lists configured on internal routers enforce rules for traffic being forwarded between internal zones and hosts.
- Incoming traffic for public-facing servers can be mediated by a load balancer, providing a corrective control to mitigate denial-of-service attacks.
- Sensors attached to mirrored switch ports enable intrusion detection for the most sensitive privilege level hosts or zones.

On each host, endpoint protection software applies a range of preventive, detective, and corrective controls to mitigate threats that have evaded network controls. Endpoint software can implement host firewalls, anti-virus, intrusion detection, and data loss prevention.

Device Attributes

Attributes determine the precise way in which a device can be placed within the network topology.

Active versus Passive

A passive security control is one that does not require any sort of client or agent configuration or host data transfer to operate. For example, network traffic can be directed or copied to a sensor and scanned by an analysis engine. This control is completely passive. Hosts on the network would be unaware that it is operating. The control has no addressable interface.

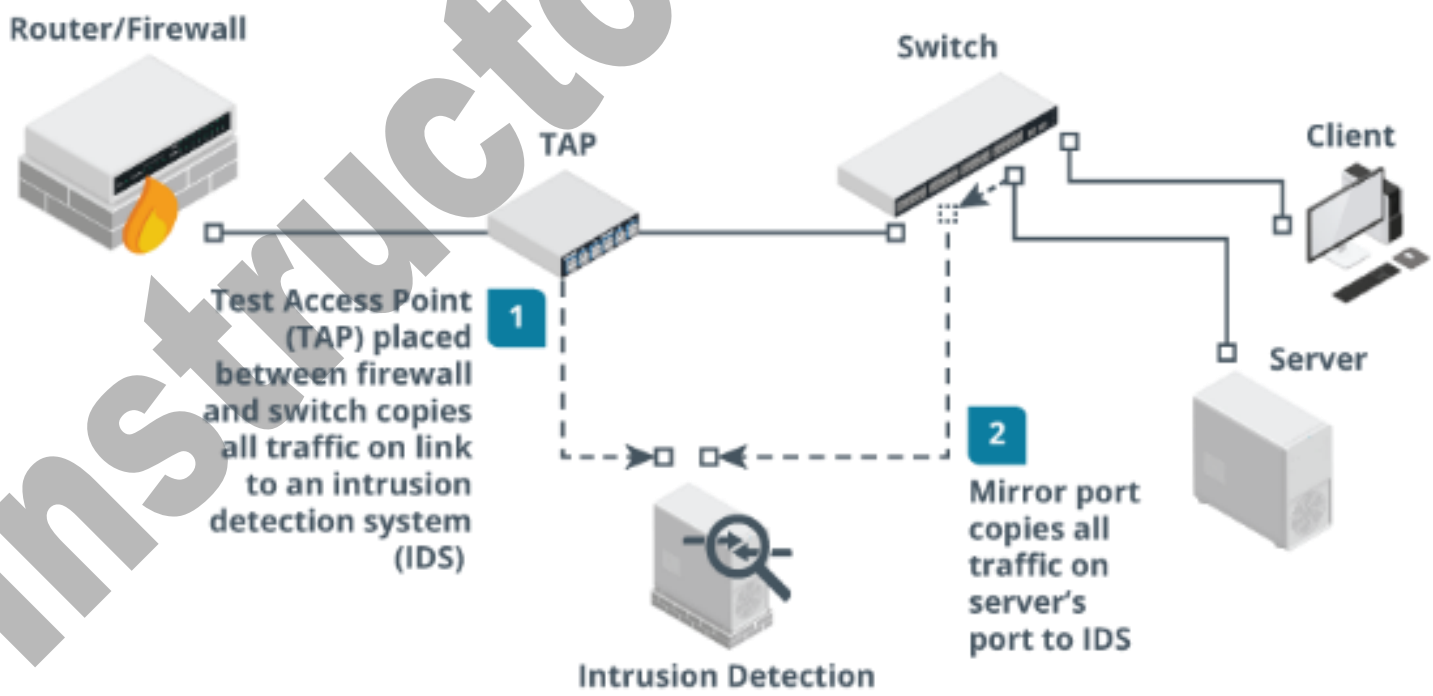
An active security control that performs scanning must be configured with credentials and access permissions and exchange data with target hosts. An active control that performs filtering requires hosts to be explicitly configured to use the control. This might mean installing agent software on the host or configuring network settings to use the control as a gateway.

Inline versus Tap/Monitor

A device that is deployed inline becomes part of the cable path. No changes in the IP or routing topology are required. The device's interfaces are not configured with MAC or IP addresses.

As an example of inline versus monitored deployment options, controls that sniff network traffic can be deployed via a sensor attached to a switch or via a tap attached to a network cable:

- SPAN (switched port analyzer)/mirror port —this means that the sensor is attached to a specially configured port on a switch that receives copies of frames addressed to nominated access ports (or all the other ports). This method is not completely reliable. Frames with errors will not be mirrored , and frames may be dropped under heavy load.
- Test access point (TAP) —this is a box with ports for incoming and outgoing network cabling and an inductor or optical splitter that physically copies the signal from the cabling to a monitor port. There are types for copper and fiber optic cabling. Unlike a SPAN, no logic decisions are made so the monitor port receives every frame—corrupt or malformed or not—and the copying is unaffected by load.



A TAP device is placed inline with the cable path, while a mirror port uses the switch to copy frames to a detection system. The router/firewall is an active control as client devices must be configured to use it for Internet access. The TAP and mirror ports are passive controls. The are completely transparent to the server and client hosts.

A security device could enter a failure state for a number of reasons. There could be a power or hardware fault, an irreconcilable policy violation, or a configuration error. Hardware failure can be caused by power surges, overheating, and physical damage. Software failure can occur because of bugs, security vulnerabilities, and compatibility issues. Configuration issues can be caused by human errors such as inattention, fatigue, or lack of training. Finally, devices or sites might be impacted by natural disasters such as floods, hurricanes, and earthquakes.

When it fails, a device can designed or configured to fail-open or fail-closed:

- Fail-open means that network or host access is preserved, if possible. This mode prioritizes availability over confidentiality and integrity. The risk of a fail-open control is that a threat actor could engineer a failure state to defeat the control.
- Fail-closed means that access is blocked or that the system enters the most secure state available, given whatever failure occurred. This mode prioritizes confidentiality and integrity over availability. The risk of a fail-closed control is system downtime.

It may or may not be possible to configure the fail mode. For example, an inline security appliance that suffers power failure will fail-closed unless there is an alternative network path. Some devices designed to be installed inline have a backup cable path that will allow a fail-open operation.

5.1.3 Practice Questions (Section Quiz)

q_ent_architecture_considerations_secp8

You are a network architect for a rapidly growing startup. The startup is planning to expand its operations and is considering a major upgrade to its network architecture.

Which of the following factors should be your primary consideration when designing the new network architecture?

Answers:

- Minimizing initial capital outlay by choosing the cheapest available hardware and software options.
- Maximizing compute resources and responsiveness, regardless of cost.
- ***Balancing costs, compute and responsiveness, scalability, availability, and resilience.**
- Prioritizing scalability and ease of deployment over all other considerations.

Explanation:

Balancing costs, compute and responsiveness, scalability, availability, and resilience is the best approach to network architecture design. This approach ensures that the network can meet the startup's current and future needs, while also considering cost-effectiveness and the ability to recover from potential failures.

Minimizing initial capital outlay is not the best choice because while minimizing initial capital outlay is important, choosing the cheapest available options could lead to performance issues, lack of scalability, and potential security risks. The long-term costs of such a decision could outweigh the initial savings.

Maximizing compute resources and responsiveness is not the best choice because while maximizing compute resources and responsiveness is important, doing so regardless of cost could lead to unnecessary expenditure. It's important to balance these factors with cost considerations.

Prioritizing scalability and ease of deployment is not the best choice because while scalability and ease of deployment are important considerations, they should not be prioritized over all other considerations. Factors such as cost, compute and responsiveness, availability, and resilience are also important and should be balanced with scalability and ease of deployment.

q_ent_architecture_defense_in_depth_secp8

You are a cybersecurity specialist for a financial institution that is planning to enhance its network security. The institution has decided to adopt a defense in depth strategy.

Which of the following approaches would BEST align with a defense in-depth strategy?

Answers:

- Implementing a single, robust firewall at the network perimeter and relying on this for all network security.
- ***Implementing multiple security measures at different network layers, including firewalls, intrusion detection systems, and regular patch management.**
- Implementing a single security measure, such as encryption, across all data and network traffic.
- Implementing a complex array of different security technologies without considering their interaction or potential redundancies.

Explanation:

Implementing multiple security measures at different network layers aligns with the defense in-depth strategy is the correct answer. This approach ensures that if one security measure fails, others are in place to provide protection.

While a robust firewall is an important part of network security, relying on a single security measure does not align with the defense in-depth strategy, which advocates for multiple layers of security.

While encryption is a valuable security measure, relying solely on it does not provide the multiple layers of security advocated for in a defense in-depth strategy.

While a defense in-depth strategy does involve implementing multiple security measures, these measures should be carefully considered and coordinated. Implementing a complex array of different security technologies without considering their interaction or potential redundancies could lead to gaps in security and inefficient use of resources.

q_ent_architecture_fail-closed_01_secp8

A hospital has implemented a security device that processes sensitive patient information. The hospital wants to ensure that in the event of a failure, the confidentiality and integrity of the patient data take priority over the system's availability.

What should the hospital set as the failure mode configuration for this security device?

Answers:

- ***The security device should be configured to fail-closed.**
- The security device should be configured to fail-open.
- The security device should be configured to actively monitor the network.
- The security device should be configured to passively monitor the network.

Explanation:

A fail-closed configuration prioritizes confidentiality and integrity over availability. In the event of a failure, a fail-closed device would block access or enter the most secure state available, protecting patient data.

A fail-open configuration would prioritize availability over confidentiality and integrity. In the event of a failure, a fail-open device would preserve network or host access, potentially exposing sensitive patient data.

While active monitoring is an important part of network security, it does not directly pertain to the failure mode of the device and would not ensure the confidentiality and integrity of patient data.

As with active monitoring, passive monitoring is important for network security, but it does not directly pertain to the failure mode of the device.

q_ent_architecture_fail-closed_02_secp8

A financial institution is implementing a new security control device to protect its network infrastructure and wants to ensure that in the event of a failure, the confidentiality and integrity of its financial data take precedence over system availability.

What should the financial institution set as the failure mode configuration for this security control device?

Answers:

- ***The security control device should be configured to fail-closed.**
- The security control device should be configured to fail-open.
- The security control device should be configured to actively monitor the network.
- The security control device should be configured to passively monitor the network.

Explanation:

Configuring the security control device to fail-closed ensures that confidentiality and integrity take precedence over availability, protecting financial data during a failure.

Fail-open configuration prioritizes availability over confidentiality/integrity and may expose sensitive financial data during a failure by preserving network/host access.

While active monitoring is important, it does not directly address the required failure mode configuration to prioritize confidentiality and integrity in this scenario.

Passive monitoring, although useful for network security, does not directly pertain to the failure mode configuration required to safeguard the confidentiality and integrity of financial data during failures.

q_ent_architecture_fail-open_01_secp8

An organization implements a new network infrastructure and plans to use an intrusion prevention system (IPS) for security. The IT manager wants to ensure that the IPS will continue to let traffic flow if it fails.

Which failure mode should the IT manager configure the IPS?

Answers:

- ***Fail-open**
- Fail-closed
- Active

- Passive

Explanation:

In a fail-open mode, if the IPS fails, it will still allow traffic to pass through, maintaining network connectivity

In a fail-closed mode, if the IPS fails, it will block all traffic, disrupting network connectivity

Active mode is an IPS operation mode, not a failure mode. In active mode, the IPS monitors traffic and blocks threats. A fail-open mode ensures traffic flow if the IPS fails.

Passive mode is an IPS operation mode, not a failure mode. In passive mode, the IPS monitors traffic and generates alerts but doesn't block threats.

q_ent_architecture_fail-open_02_secp8

An organization is implementing an Intrusion Prevention System (IPS) as part of its efforts to secure its enterprise infrastructure. The IT manager is considering the failure modes of the IPS and is deciding between a fail-open and a fail-closed configuration.

What are the implications of each configuration on network traffic in the event of a system failure?

Answers:

- ***Fail-open will allow all traffic, while fail-closed will block all traffic.**
- Fail-open will block all traffic, while fail-closed will allow all traffic.
- Both fail-open and fail-closed will block all traffic.
- Both fail-open and fail-closed will allow all traffic.

Explanation:

An IPS can either allow all traffic through without disruption but with a risk of malware (fail-open) or block all traffic without malware but with a risk of disruption (fail-closed).

In the event of a system failure, a fail-open configuration allows all traffic, while a fail-closed configuration blocks all traffic.

Even if the system fails, a fail-open configuration allows all traffic to pass through, ensuring that there is no disruption to the flow of data and information.

If the system fails, a fail-closed configuration blocks all traffic from passing through, ensuring that no malware or other harmful content can enter the network.

q_ent_architecture_inline_mode_secp8

The IT manager of a medium-sized organization is designing a new network infrastructure to secure its enterprise infrastructure by implementing an Intrusion Prevention System (IPS) and an Intrusion Detection System (IDS). The manager is considering different deployment methods for the IPS/IDS to optimize their effectiveness.

The organization's network includes multiple security zones, a virtual private network (VPN) for remote access, and a web application firewall (WAF).

Which deployment method provides the MOST comprehensive protection in this scenario?

Answers:

- ***Deploy the IPS/IDS devices in inline mode at the network perimeter.**
- Deploy the IPS/IDS devices in passive mode within the internal network.
- Deploy the IPS/IDS devices in tap/monitor mode at the entry and exit points of the VPN tunnel.
- Deploy the IPS/IDS devices in inline mode next to the WAF.

Explanation:

Deploying the IPS/IDS devices in inline mode at the network perimeter allows for real-time analysis and reaction to potential threats, providing comprehensive protection for all inbound and outbound network traffic.

While deploying the IPS/IDS devices in passive mode inside the internal network provides visibility into internal threats, it does not provide real-time threat mitigation or cover inbound and outbound traffic.

IPS/IDS devices in tap/monitor mode at the entry and exit points of the VPN tunnel can help monitor remote access but do not protect all network traffic.

Although deploying the IPS/IDS devices in inline mode next to the WAF can enhance the security of web applications, it does not protect all network traffic.

q_ent_architecture_load_balancer_secp8

A small start-up has recently launched its first web application. To ensure high availability and to handle potential traffic spikes, the start-up decides to implement a load balancer in its network infrastructure.

The network technician must secure the load balancer against basic threats.

What is the fundamental step the network technician should take to secure the load balancer?

Answers:

- ***Disable unnecessary services on the load balancer.**
- Implement an intrusion detection system (IDS) alongside the load balancer.
- Configure the load balancer to operate in fail-closed mode.
- Enable all available features on the load balancer.

Explanation:

Disabling unnecessary services on the load balancer is a fundamental step in reducing the attack surface and enhancing security.

While implementing an IDS can enhance security, it is not a fundamental step when securing a load balancer and might be an overkill for a small start-up.

Configuring the load balancer to operate in a fail-closed mode can prevent unfiltered network traffic in case of device failure. However, it is not the most basic step in securing a load balancer.

Enabling all available features on the load balancer is not a good security practice. It could potentially open up unnecessary vulnerabilities and complicate the configuration.

q_ent_architecture_network_nodes_secp8

You are a network engineer for a multinational corporation. The corporation is planning to expand its operations to a new location and you are tasked with designing the network for the new site. The network should be robust, scalable, and secure.

Which of the following approaches to setting up network nodes at the new site would best meet these requirements?

Answers:

- Setting up a single powerful server to handle all network functions.
- ***Setting up multiple network nodes, each dedicated to a specific function such as routing, switching, and firewalling.**
- Setting up a single network node with minimal functionality to reduce costs.
- Setting up multiple network nodes with redundant functionality to ensure high availability.

Explanation:

Setting up multiple network nodes, each dedicated to a specific function, is the correct answer and allows for better performance, scalability, and security. Each node can be optimized for its specific function, and if one node fails, the impact on the overall network is minimized.

Setting up a single power server is not the best choice because a single server handling all network functions could become a bottleneck, affecting network performance. Additionally, if this server fails, all network functions would be affected, leading to significant downtime.

Setting up a single network node is not the best choice because while it may reduce initial costs, a single network node with minimal functionality would likely not be able to handle the network demands of a multinational corporation. This could lead to poor network performance and potential security risks.

Setting up multiple network nodes with redundant functionality is not the best choice because while redundancy is important for high availability, having multiple network nodes with redundant functionality could lead to unnecessary complexity and costs. It would be more efficient to have each network node dedicated to a specific function, with appropriate backup and failover mechanisms in place.

q_ent_architecture_network_protocols_secp8

You are a network engineer for a global company that is implementing a new real-time data processing system. This system requires efficient and reliable data transfer between different network segments.

Which of the following network components would be most critical in ensuring the efficient and reliable transfer of real-time data in this scenario?

Answers:

- Application protocols
- Domain Name System (DNS) servers
- ***Transport protocols**
- Wireless access points

Explanation:

Transport protocols is the correct answer. Transport protocols, such as the Transmission Control Protocol (TCP) and the User Datagram Protocol (UDP), operate at the transport layer (Layer 4) of the OSI model. They are responsible for the end-to-end transfer of data between systems and can provide mechanisms for ensuring reliable data transfer, which is critical for real-time data processing systems.

Application protocols are not the best choice because they operate at the application layer (Layer 7) of the OSI model and are more concerned with the format and control of the data exchange between applications, not the efficient and reliable transfer of data between network segments.

Domain Name System (DNS) servers are not the best choice because their primary function is to translate domain names into IP addresses, not to ensure the efficient and reliable transfer of real-time data between network segments.

Wireless access points are not the best choice because their primary function is to provide a bridge between a wired network and wireless devices. While they do play a role in data transfer, they do not have the same level of control over the efficiency and reliability of data transfer as transport protocols.

q_ent_architecture_osi_secp8

You are a network architect for a large organization. The organization is planning to upgrade its network infrastructure to support a new business application. The application requires high availability, secure data transfer, and efficient handling of large data volumes.

Which of the following network design considerations best aligns with the requirements of the new business application?

Answers:

- Implementing a flat network design with all devices on the same network segment.
- ***Implementing a layered network design based on the OSI model with appropriate security controls at each layer.**
- Implementing a network design with minimal use of routers to reduce complexity.
- Implementing a network design that prioritizes cost reduction over scalability and resilience.

Explanation:

A layered network design based on the OSI model is the correct answer. The OSI model allows for the implementation of appropriate security controls at each layer, from the physical layer up to the application layer. This design also supports high availability and efficient handling of large data volumes by allowing for network segmentation and the use of specialized devices and protocols at each layer.

A flat network design is not the best choice because a flat network design does not provide the necessary segmentation for secure data transfer and efficient handling of large data volumes. In a flat network, all devices are on the same network segment, which can lead to performance issues and increased security risks.

Minimal use of routers is not the best choice because, while it may reduce complexity, it does not support high availability or efficient handling of large data volumes. Routers play a crucial role in directing network traffic and segmenting the network, which are important for the requirements of the new business application.

Prioritizing cost reduction over scalability and resilience is not the best choice because while cost reduction is an important consideration, it should not be prioritized over scalability and resilience, especially for a business application that requires high availability and secure data transfer. A network design that lacks scalability and resilience may result in higher costs in the long run due to potential downtime and security incidents.

q_ent_architecture_risk_transference_secp8

As a senior network architect at your company, you have been tasked with evaluating the current network architecture and proposing changes to improve security and efficiency.

The company has been experiencing frequent network outages due to an outdated infrastructure, which has led to significant financial losses. The board of directors is concerned about the costs associated with a complete network overhaul and is considering other options.

Which of the following is the MOST appropriate course of action?

Answers:

- Implement a complete network overhaul immediately, regardless of the costs.
- Do nothing and continue with the current network architecture.
- ***Transfer the risk by outsourcing the network management to a third-party service provider.**
- Invest in minor upgrades to the current network infrastructure.

Explanation:

Transferring the risk by outsourcing the network management to a third-party service provider is the correct answer. This approach allows the company to leverage the expertise of a third-party provider, potentially improving network stability and security. It also transfers the risk associated with network management to the third-party provider, aligning with the concept of risk transference.

Implementing a complete network overhaul immediately, regardless of the costs, may not be the best solution. While it could potentially solve the current issues, it may also introduce new ones and could be financially burdensome for the company. This approach does not consider the risk transference option.

Doing nothing and continuing with the current network architecture is not a viable option. The frequent network outages are causing significant financial losses and damaging the company's reputation. This approach ignores the problem and does not consider risk transference.

Investing in minor upgrades to the current network infrastructure may not be sufficient to address the frequent network outages. While this approach may improve the situation in the short term, it does not provide a long-term solution and does not consider risk transference.

q_ent_architecture_tap_secp8

You are a network engineer for a large corporation that is planning to implement a new intrusion detection system (IDS). The corporation has a high volume of network traffic and requires real-time monitoring for potential security threats.

Which of the following approaches to integrating the IDS into the corporation's network would best meet these requirements?

Answers:

- Connecting the IDS directly to the corporation's main router.
- ***Using a Test Access Point (TAP) device to provide the IDS with a copy of the network traffic.**
- Connecting the IDS to a switch and configuring the switch to mirror all network traffic to the IDS.
- Connecting the IDS to a random network node to minimize impact on network performance.

Explanation:

Using a Test Access Point (TAP) device is the correct answer. A TAP device allows the IDS to receive a copy of all network traffic without impacting network performance. This approach enables real-time monitoring and is suitable for networks with high traffic volumes.

Connecting the IDS directly to the corporation's main router is not the best choice because connecting the IDS directly to the corporation's main router could impact network performance. The router may not be able to handle the additional load of forwarding all network traffic to the IDS.

Connecting the IDS to a switch and configuring the switch to mirror all network traffic to the IDS is not the best choice because while a switch can be configured to mirror all network traffic to the IDS, this approach could impact the switch's performance and may not be suitable for networks with high traffic volumes.

Connecting the IDS to a random network node to minimize impact on network performance is not the best choice because connecting the IDS to a random network node would not ensure that the IDS receives all network traffic. This approach could result in incomplete monitoring and potential security risks.

5.2 Security Appliances

As you study this section, answer the following questions:

- What are the benefits and risks of using proxy servers?
- What is the purpose of a content filtering server?
- What are the uses of a screened subnet?
- Why is a honeynet useful?
- What are the features of an all-in-one security appliance?
- What size organization should employ a all-in-one security appliance?

In this section, you will learn to:

- Configure a security appliance.
- Configure network security appliance access.

The key terms for this section include:

Term	Definition
Security zone	Portions of the network or system that have specific security concerns or requirements.
Wireless network	A network that does not require a physical connection.
Guest network	A network that grants internet access only to guest users. A guest network has a firewall to regulate guest user access.
Honeynet	A host (honeypot), network (honeynet), file (honeyfile), or credential/token (honeytoken) set up with the purpose of luring attackers away from assets of actual value and/or discovering attack strategies and weaknesses in the security configuration.
Ad hoc	A decentralized network that allows connections without a traditional base station or router. It allows users to connect two or more devices directly to each other for a specific purpose.

DNS sinkhole	A temporary DNS record that redirects malicious traffic to a controlled IP address.
Jump server	A hardened server that provides access to other hosts.
Agent-based filtering	Agent-based web filtering involves installing a software agent on desktop computers, laptops, and mobile devices. The agents enforce compliance with the organization's web filtering policies.
Screened subnet	A network that contains publicly accessible resources and is located between the private network and an untrusted network, such as the internet. It is protected by a firewall.
Proxy server	A type of firewall that stands as an intermediary between clients requesting resources from other servers.
Internet content filter	Software used to monitor and restrict content delivered across the web to an end user.
Fake telemetry	Deception strategy that returns spoofed data in response to network probes.
All-in-one security appliance	An appliance that combines many security functions into a single device.
Application-aware devices	A device that has the ability to analyze and manage network traffic based on the application-layer protocol.

This section helps you prepare for the following certification exam objectives:

Exam	Objective

CompTIA Security+ SY0-701	1.2 Summarize fundamental security concepts.
	• Deception and disruption technology
	  ○ Honeypot
	  ○ Honeynet
	  ○ Honeyfile
	  ○ Honeytoken
	3.2 Given a scenario, apply security principles to secure enterprise infrastructure.
	• Infrastructure considerations
	  ○ Security zones
	• Failure modes

	○ Fail-open ○ Fail-closed • Network appliances ○ Jump server ○ Proxy server ○ Load balancer ○ Sensors 4.5 Given a scenario, modify enterprise capabilities to enhance security. • Web filter ○ Agent-based ○ Centralized proxy ○ Universal Resource Locator (URL) scanning ○ Content categorization ○ Block rules ○ Reputation
TestOut Security Pro	2.1 Harden Physical Access 2.1.2 Install and Configure a Security Appliance 2.1.4 Create and Configure a screened subnet

5.2.1 Security Appliances (Lesson Video)

Transcript:

In network security, many appliances are available to help secure your network. The size, needs, and resources of your organization will be factors in determining which ones to implement for your network. In this lesson, we'll look at a few of these options.

Let's start with proxy servers. A proxy is a person who has the authority to act on behalf of another person.
Similarly, a proxy server acts on behalf of a client or user when attempting to access resources over the internet. The proxy server, in this position of an intermediary, provides a layer of protection to the client. A proxy server works on a store-and-forward model. This means the proxy deconstructs each packet, performs analysis, then rebuilds the packet and forwards it on if it conforms to the rules it's been configured with.
The main benefit of a proxy is that client computers connect to a specified point on the perimeter network for web access. This provides a degree of traffic management and security. Proxy servers can also provide anonymity for users by masking their IP addresses. In addition, most web proxy servers provide caching engines; the proxy retains frequently requested web pages, eliminating the need to re-fetch those pages for subsequent requests.
Proxy servers are also often used for content filtering and monitoring. They can block certain websites or filter out malicious content before it reaches the client. Proxy servers can even distribute incoming network traffic across multiple servers, helping to balance the load and improve the overall performance and reliability of a network.
The next appliance is a jump server. A jump server is a hardened server that provides access to other hosts. Jump servers are often used for administrative tasks, where administrators connect to the jump server first and then use it to access other internal systems, like servers or devices.
A jump server is primarily used to enhance security by controlling access to sensitive resources. It acts as a gateway to access certain systems kept isolated from the external network. The jump server is typically locked down and secured to a higher degree, ensuring that only authorized users can access it, reducing the risk of unauthorized access to critical systems.
Now, let's talk about load balancers. While primarily used to distribute network traffic across multiple servers to optimize performance, a load balancer can also serve as a security appliance in certain scenarios. A load balancer distributes

client requests across available server nodes in a farm or pool. This is used to provision services that can scale from light to heavy loads and to provide mitigation against denial-of-service attacks.
A load balancer also provides fault tolerance. When there are several servers in a farm, all identified by a single name or IP address via a load balancer, if one server stops working, client requests can be sent to another server in the same group.
A load balancer can be deployed in any situation where there are multiple servers providing the same function. Examples include web servers, front-end email servers, web conferencing, and streaming media servers.
There are two main types of load balancers: layer 4 and layer 7. A layer 4 load balancer makes forwarding decisions on IP address and TCP/UPD port values, working at the transport layer of the OSI model. A layer 7 load balancer, or content switch, makes forwarding decisions based on application-level data, such as a request for a particular URL web address or data types like video or audio streaming, which requires more complex logic.
Load balancers can also include a Web Application Firewall that provides protection against common web application attacks. Modern load balancers often include features for traffic inspection and filtering. They can analyze incoming traffic for suspicious patterns, such as unusual request rates or malicious payloads. Traffic from potentially harmful sources can be dropped or redirected for further analysis.
Another network security appliance is a packet sniffer, which is referred to as a sensor. Typically, the packet capture sensor is placed behind a firewall or close to a server of particular importance. The idea is to identify malicious traffic that has managed to get past the firewall. A single sniffer can record a large amount of traffic data, so don't put multiple sensors all over the network without provisioning the resources to manage them properly. Depending on network size and resources, one or only a few sensors are typically deployed to monitor key assets or network paths.
The traffic captured by each sensor is transferred to a host or appliance running an intrusion detection system, or IDS, such as Snort, Suricata, or Zeek. When traffic matches a detection signature, the IDS raises an alert or generates a log entry but does not block the source host. This type of passive sensor doesn't slow down traffic and is undetectable by the attacker.
An IDS is used to identify and log hosts and applications and to detect password-guessing attempts, port scans, worms, backdoor applications, malformed packets or sessions, and other policy violations.
The last appliance we'll look at in this lesson is an all-in-one security appliance. An all-in-one security appliance incorporates multiple security functions into a single piece of hardware.
Unified Threat Management, or UTM, is the most common all-in-one appliance. UTM puts several key security components into a single device, usually managed using a web interface.
Let's look at some of the functionality commonly implemented in all-in-one security devices. One of the first features is URL filtering, which prevents users from accessing URL categories restricted by the organization. These often include pornographic, shopping, and gambling sites.
Another feature is content inspection. This helps to ensure that HTTP connections and content meet certain criteria. For example, many content filters actively monitor data streams by inspecting the packets in search of viruses, Trojans, worms, and other malicious code.
These devices also include a spam filter to reduce the chance that your users' mailboxes will fill up with junk email. The UTM will also probably include a firewall so you can set up rules and log traffic to and from the network. Many devices include an integrated intrusion detection or prevention system that alerts you if a network attack attempt is detected or prevented.
An all-in-one device typically contains networking features as well as UTM features. These network features include an integrated switch. For small and remote offices that only have a handful of systems, a small integrated switch provides all the connectivity required. As part of switching, the device may include a network router that allows you to connect to a network backbone using an uplink port.
The device may also support traffic shaping to prioritize one type of traffic over another. For example, if the organization is using voice-over IP phones, the all-in-one appliance can give voice traffic priority over normal data traffic.
And that's it for this lesson. In this lesson, we discussed a few security appliance options. First, we talked about proxy servers and how they work as middlemen between clients and internet resources. Then, we looked at jump servers that are used to control access to sensitive resources. Then, we reviewed load balancers and what role they can play in security. After that, we looked at sensors and how they record traffic data and supply that information to an IDS, which flags anything with a matching detection signature. We ended this lesson by discussing an all-in-one security appliance called a Unified Threat Management appliance, which can combine multiple devices into one appliance.

5.2.2 Security Solutions (Lesson Video)

Transcript:

Many of us take for granted the clean water we get from our faucets every day. Before we take a drink, the dangerous contaminants have been filtered out, leaving us with only what we want. One very important security solution for networks is filtering: content filtering and web filtering. Just like filtering out dangerous contaminants from our drinking water, content filters and web filters filter out dangerous contaminants to our networks and users. Let's take a closer look.

Let's start with content filtering servers. Content filtering servers typically have one or two configurations. Either you allow all content except for what you decide to ban, or you block all content except for what you decide to allow. These controls are implemented through security levels, allow lists, deny lists, and category levels.

A content filter is designed to give network administrators and management the ability to block unwanted or inappropriate website browsing. For example, several organizations have guidelines stating that users can't visit adult sites, gambling, or shopping sites while at work. A content filter can be put in place, and the network administrator can configure the filter to prevent users from visiting these types of sites.

Most often, the content filter allows everything except sites and categories that are blocked via a denylist. For additional flexibility, security groups can be configured to allow or prevent site access by group.

New websites are created every day, so the filters must be updated regularly, like virus definitions. Most content filtering servers have an online subscription service to update websites and website categories at certain intervals, usually daily or weekly.

Now, web filtering plays a pivotal role in safeguarding an organization's network. Its primary function is to block users from accessing malicious or inappropriate websites, thereby protecting the network from potential threats.

Web filters analyze web traffic, often in real-time, and can restrict access based on various criteria such as URL, IP address, content category, or even specific keywords.

Now, let's look at two different approaches to web filtering: agent-based and centralized. The first approach is focused on filtering at each endpoint. The second filters from a centralized proxy server that endpoints are connected to.

Agent-based web filtering involves installing a software agent on desktop computers, laptops, and mobile devices. The agents enforce compliance with the organization's web filtering policies. Agents communicate with a centralized management server to retrieve filtering policies and rules and then apply them locally on the device. Agent-based solutions typically leverage cloud platforms to ensure they can communicate with devices regardless of the network they're connected to. This means filtering policies remain in effect even when users are off the corporate network, such as when working from home or traveling.

Because filtering occurs locally on the device, agent-based methods often provide more granular control, such as filtering HTTPS traffic or applying different filtering rules for different applications. Agent-based filtering can also provide detailed reporting and analytics.

In a centralized approach, a proxy server performs content filtering by analyzing web requests from users and determining whether to permit or deny access based on established policies. A centralized proxy server acts as an intermediary between end users and the internet. Beyond blocking unwanted or harmful content, a centralized proxy server can also perform detailed logging and reporting of web activity.

A centralized proxy server employs various techniques to protect web traffic and ensure the safety of an organization's network. A proxy server can perform URL scanning, which involves blocking URLs known to host malicious content, are inappropriate, or violate the company's policies.

Proxy servers also allow content categorization. This means that websites can be classified into various categories like social networking, gambling, webmail, and many others. Organizations can define rules to allow or deny access based on these categories.

Another technique proxy servers can implement is block rules. For example, an organization could block all .exe downloads or certain domains or content categories.

Proxy servers can even incorporate reputation-based filtering, which leverages continually updated databases that score websites based on their observed behavior and history. Sites known for hosting malware, engaging in phishing attacks, or distributing spam, for instance, would have a poor reputation score and could be automatically blocked.

Content and web filtering aren't without potential issues and challenges. One common problem is overblocking or underblocking. Overblocking occurs when the filter is too restrictive, inadvertently blocking access to legitimate and useful websites and negatively impacting employee productivity.

Underblocking, on the other hand, occurs when the filter allows access to potentially harmful or inappropriate websites.

Another issue is the handling of encrypted traffic like HTTPS. Without proper configuration, web filters may be unable to inspect encrypted traffic, representing most modern web traffic.

Well, that's it for this lesson. In this lesson, we discussed security solutions based on content and web filtering. We looked at how content filters can either allow everything except what you specifically ban or they can ban everything

except what's specifically allowed. We then looked at two approaches to web filtering: agent-based, which is applied to endpoints, and centralized, which is provided through a proxy server that network traffic flows through. We ended the lesson by looking at the challenge of not overblocking or underblocking when applying filters so that the network is protected, and users can do their work and access their resources.

5.2.3 Security Solution Facts

This lesson covers the following topics:

- Security appliances
- Security solutions

Security Appliances

In network security, there are many appliances available to help secure your network. The size, needs, and resources of your organization will be factors in determining which ones to implement for your network. The following table includes several security appliances.

Appliance	Description
Proxy server	A proxy server acts on behalf of a client or user when attempting to access resources over the internet. The proxy server, in this position of an intermediary, provides a layer of protection to the client. A proxy server works on a store-and-forward model. This means the proxy deconstructs each packet, performs analysis, then rebuilds the packet and forwards it on, if it conforms to the rules it's been configured with. Client computers connect to a specified point on the perimeter network for web access. Benefits a proxy server can provide: • Traffic management • Protection • Anonymity for users by masking their IP addresses • Caching engines • Content filtering • Content monitoring • Incoming network traffic distribution across multiple servers to help balance the load
Jump server	A jump server is a hardened server that provides access to other hosts. Jump servers are often used for administrative tasks where administrators connect to the jump server first and then use it to access other internal systems, like servers or devices. A jump server is primarily used to enhance security by controlling access to sensitive resources. It acts as a gateway to access certain systems that are kept isolated from the external network. The jump server is typically locked down and secured to a higher degree, ensuring that only authorized users can access it, reducing the risk of unauthorized access to critical systems.
Load balancer	A load balancer, while primarily used to distribute network traffic across multiple servers to optimize performance, can also serve as a security appliance in certain scenarios. A load balancer distributes client requests across available server nodes in a farm or pool. This is used to provision services that can scale from light to heavy loads and to provide mitigation against denial-of-service attacks. A load balancer also provides fault tolerance. If there are multiple servers available in a farm all addressed by a single name/IP address via a load balancer, then if a single server fails, client

Appliance	Description
	requests can be forwarded to another server in the farm. A load balancer can be deployed in any situation where there are multiple servers providing the same function. Examples include web servers, front-end email servers, web conferencing, video conferencing, and streaming media servers. There are two main types of load balancers: • Layer 4 — A layer 4 load balancer makes forwarding decisions on IP address and TCP/UPD port values, working at the transport layer of the OSI model. • Layer 7 — A layer 7 load balancer, or content switch, makes forwarding decisions based on application-level data, such as a request for a particular URL web address or data types like video or audio streaming, which requires more complex logic. Load balancers can also include a Web Application Firewall (WAF) that provides protection against common web application attacks. Modern load balancers often include features for traffic inspection and filtering. They can analyze incoming traffic for suspicious patterns, such as unusual request rates or malicious payloads. Traffic from potentially harmful sources can be dropped or redirected for further analysis.
Sensor	A packet sniffer is referred to as a sensor. Typically, the packet capture sensor is placed behind a firewall or close to a server of particular importance. The idea is to identify malicious traffic that has managed to get past the firewall. A single sniffer can record a large amount of traffic data so it's best to not put multiple sensors all over the network without provisioning the resources to manage them properly. Depending on network size and resources, one or only a few sensors are deployed to monitor key assets or network paths. The traffic captured by each sensor is transferred to a host or appliance running an intrusion detection system (IDS), such as Snort, Suricata, or Zeek. When traffic matches a detection signature, the IDS raises an alert or generates a log entry but does not block the source host. This type of passive sensor does not slow down traffic and is undetectable by the attacker. An IDS is used to identify and log hosts and applications and to detect password-guessing attempts, port scans, worms, backdoor applications, malformed packets or sessions, and other policy violations.
All-in-one security appliance	An all-in-one security appliance incorporates multiple security functions into a single piece of hardware. Unified Threat Management, or UTM, is the most common all-in-one appliance. UTM puts several key security components into a single device that's usually managed using a web interface. A manufacturer subscription for updates may also be required. Commonly implemented functionality of all-in-one-security devices include the following: • URL filtering—prevents users from accessing URL restricted categories. • Content inspection—helps ensure HTTP connections and content meet specified criteria. For example, many content filters actively monitor data streams by inspecting the packets in search of viruses, Trojans, worms, and other malicious code. • Spam filtering—reduces junk mail in mailboxes of users. • Firewall—can be configured with rules and used to log traffic to and from the network. • Intrusion detection system—An IDS sends an alert if a network attack is detected. • Intrusion prevention system—An IPS sends an alert if a network attack is detected or prevented.

Appliance	Description
	A UTM usually includes networking features as well, such as the following: • Switch • Router • Traffic shaping management

Failure Modes

A security device could enter a failure state for a number of reasons. There could be a power or hardware fault, an irreconcilable policy violation, or a configuration error. Hardware failure can be caused by power surges, overheating, and physical damage. Software failure can occur because of bugs, security vulnerabilities, and compatibility issues. Configuration issues can be caused by human errors such as inattention, fatigue, or lack of training. Finally, devices or sites might be impacted by natural disasters such as floods, hurricanes, and earthquakes.

When it fails, a device can designed or configured to fail-open or fail-closed:

- Fail-open means that network or host access is preserved, if possible. This mode prioritizes availability over confidentiality and integrity. The risk of a fail-open control is that a threat actor could engineer a failure state to defeat the control.
- Fail-closed means that access is blocked or that the system enters the most secure state available, given whatever failure occurred. This mode prioritizes confidentiality and integrity over availability. The risk of a fail-closed control is system downtime.

It may or may not be possible to configure the fail mode. For example, an inline security appliance that suffers power failure will fail-closed unless there is an alternative network path. Some devices designed to be installed inline have a backup cable path that will allow a fail-open operation.

Security Solutions

Content Filtering Server

A content filtering server can deny or allow users access to certain websites. Content filtering servers typically have one or two configurations:

- Allow all content except for what you decide to ban
- Block all content except for what you decided to allow.

These controls are implemented through security levels, allow lists, deny lists, and category levels.

A content filter is designed to give network administrators and management the ability to block unwanted or inappropriate website browsing. For example, several organizations have guidelines stating that users can't visit adult sites, gambling, or shopping sites while at work. A content filter can be put in place, and the network administrator can configure the filter to prevent users from visiting these types of sites.
Most often, the content filter allows everything except sites and categories that are blocked via a deny list. For additional flexibility, security groups can be configured to allow or prevent site access by group.
New websites are created every day, so the filters must be updated regularly, like virus definitions. Most content filtering

servers have an online subscription service to update websites and website categories at certain intervals, usually daily or weekly.

Web Filtering

Web filtering plays a pivotal role in safeguarding an organization's network. Its primary function is to block users from accessing malicious or inappropriate websites, thereby protecting the network from potential threats. Web filters analyze web traffic, often in real time, and can restrict access based on various criteria such as URL, IP address, content category, or even specific key words.
Two approaches to web filtering include:

- Agent-based which is focused on filtering at each endpoint.
- Centralized filters from a centralized proxy server to which endpoints are connected.

Agent-Based Filtering

Agent-based web filtering involves installing a software agent on desktop computers, laptops, and mobile devices. The agents enforce compliance with the organization's web filtering policies. Agents communicate with a centralized management server to retrieve filtering policies and rules and then apply them locally on the device. Agent-based solutions typically leverage cloud platforms to ensure they can communicate with devices regardless of the network they are connected to. This means filtering policies remain in effect even when users are off the corporate network, such as when working from home or traveling. Because filtering occurs locally on the device, agent-based methods often provide more granular control, such as filtering HTTPS traffic or applying different filtering rules for different applications. Agent-based filtering can also provide detailed reporting and analytics.

Centralized Web Filtering

In a centralized approach, a proxy server performs content filtering by analyzing web requests from users and determine whether to permit or deny access based on established policies. A centralized proxy server acts as an intermediary between end users and the internet. Beyond blocking unwanted or harmful content, a centralized proxy server can also perform detailed logging and reporting of web activity.
A centralized proxy server employs various techniques to protect web traffic and ensure the safety of an organization's network. Examples of these techniques include:

- URL scanning—involves blocking URLs known to host malicious content, are inappropriate, or violate the company's policies.
- Content categorization—websites can be classified into various categories like social networking, gambling, webmail, and many others.
- Block rules—organizations can define rules to allow or deny access based on things like content categories, downloads of file types like .exe, or certain domains.
- Reputation-based filtering—leverages continually updated databases that score websites based on their observed behavior and history. Sites known for hosting malware, engaging in phishing attacks, or distributing spam, for instance, would have a poor reputation score and could be automatically blocked.

Web Filtering Challenges

Content and web filtering are not without potential issues and challenges. Three common challenges include:

- Overblocking which occurs when the filter is too restrictive, inadvertently blocking access to legitimate and useful websites and negatively impacting employee productivity.
- Underblocking which occurs when the filter allows access to potentially harmful or inappropriate websites.
- Handling of encrypted traffic like HTTPS. Without proper configuration, web filters may be unable to inspect encrypted traffic, representing most modern web traffic.

DNS Filtering

Domain Name System (DNS) filtering is a technique that blocks or allows access to specific websites by controlling the resolution of domain names into IP addresses. It operates on the principle that for a device to access a website, it must first resolve its domain name into its associated IP address, a process managed by DNS. When a request is made to resolve a website URI, the DNS filter checks the request against a database of domain names. If the domain is associated with malicious activities or is on an unapproved list for any reason, the filter blocks the request, preventing access to the potentially harmful website.

DNS filtering is highly effective for many reasons. A few are listed below:

- It provides a proactive defense mechanism, blocking access to known phishing sites, malware distribution sites, and other malicious online destinations.
- It can help enforce an organization's acceptable use policies (AUPs) by blocking access to inappropriate or distracting websites and ensuring that the internet is used responsibly and productively.
- It can protect all devices connected to a network, including IoT devices, providing an extra layer of security.
- It is a simple solution that is easy to implement and presents minimal risk, making it a cost-effective security control suitable for networks of any size.

While DNS filtering is highly effective, it must be combined with other security measures for comprehensive protection.

5.2.4 Security Zones (Lesson Video)

Transcript:

In this lesson, we're going to discuss security zones. Security zones are portions of the network that have specific security concerns or requirements. All devices within the same zone have the same security access and protection needs.

These zones are often separated by a traffic control device, such as a firewall or a router, that filters incoming and outbound traffic.
For example, you can define a zone that includes all hosts on your private network that need to be protected from the internet. You can also define a zone within your network for controlled access to specific servers that hold sensitive information.
There are several types of security zones that can be implemented.
Let's start with a security zone known as a screened subnet. A screened subnet is used as a public-facing accessible network. It acts as a buffer and a barrier to your internal production network, which is accessible from the internet. A screened subnet can be configured using either one or two firewalls and acts as the middleman between the internet and your internal network.
For example, a screened subnet is often used to allow employees access to critical network components, such as email servers, VPN connections, and internal web servers, from outside the company. Screened subnets also provide customer access to a company's products, such as software.
To do this, the firewall allows traffic from the internet into the screened subnet and enables those resources to access resources on the production network. The servers placed in the screened subnet are typically configured as a bastion host. A bastion host is a server that's specifically designed and configured to withstand attacks. In general, they're specific-purpose systems that host a single application and are hardened to resist attacks.
Another type of security zone is a wireless network zone. A wireless network zone is a broadcasted network connection used within an organization where users don't need a physical connection to a network port to connect to internal resources.
Instead, they use a wireless connection on their device to connect to a wireless access point. For internal users, the effect is the same as if the user's device has a physical connection and provides access to internal resources.
Several organizations also create a guest network that allows non-internal staff to access the internet. In some cases, guests may also be granted access to a few limited internal resources.

A honeynet contains servers designed to trap attackers. The servers, or honeypots, contain intentional vulnerabilities to lure attackers. Attackers believe they're accessing vulnerable systems, but they're really inside a trap. Honeypots are designed to mimic production servers that would be found in a typical organization. Of course, they contain no real company information, so there's little risk of exposure. The honeypots track an attacker's activity and can generate extremely useful security information.

An ad hoc network is a decentralized network that allows connections without a traditional base station or router. It allows users to connect two or more devices directly to each other for a specific purpose. Ad hoc is a Latin term that translates to "for this," and ad hoc networks are usually temporary solutions for a specific task.

Ad hoc connections can be wired or wireless. If you're connecting two systems with an Ethernet cable, it must be a crossover cable. An ad hoc network can also be created using Wi-Fi. Of course, the Wi-Fi parameters and protocols must match and be compatible with each other, including the SSID, security, and encryption settings.

Network Address Translation, or NAT, provides global IP address conversion for the entire network and is usually performed by your internet gateway, or NAT server. NAT allows network administrators to manage IP addresses within the internal network using whatever private IPs they want. When a user needs to access the internet, the NAT server then translates these internal private IP addresses to public IP addresses that the internet can recognize.

The organization's internet service provider can supply internet routable IP addresses and assign them to the organization. When information returns, the internet gateway converts the public address back to the private address and sends it on to the private network and user.

That's it for this lesson. In this lesson, we discussed several types of security zones. First, we discussed screened subnets, where servers are placed for public access. Next, we discussed wireless zones, which allow employees to access internal resources using Wi-Fi and provide guest networks that limit access. Then, we talked about honeynets, which are used to trap attackers and gather information. We ended this lesson by discussing ad hoc networks, which are used for temporary connectivity between two or more devices, and NAT servers, which convert private IP addresses to public IP addresses.

5.2.5 Security Zone Facts

This lesson covers the following topics:

- Security zones
- Security zone networks
- Common security zones

Security Zones

Security zones are portions of the network or system that have specific security concerns or requirements. All devices with the same zone have the same security access and security protection needs. These zones are often separated by a traffic control device, such as a firewall or a router, that filters incoming and outbound traffic. For example, you can define a zone that includes all hosts on your private network protected from the internet. You can also define a zone within your network for controlled access to specific servers that hold sensitive information.

Security Zone Networks

The following table lists the types of networks found in your security zones:

Network Type	Description
Wireless	A wirelessly broadcasted network is used on most internal networks so that internal users do not require a physical connection to a router or switch.

Guest	A guest network at an organization often grants internet access only to guest users, but it also has some type of firewall to regulate that access. There could be limited internal resources made available on a guest network. Normally, it is just a way for guests to access the internet without being allowed on the intranet or internal network.
Honeynet	A honeynet is a special network created to trap potential attackers. Honeynets have vulnerabilities that lure attacks so that you can track their actions and protect your real network. Honeynets can generate extremely useful security information.
Ad hoc	An ad hoc network is a decentralized network that allows connections without a traditional base station or router. It allows users to connect two or more devices directly to each other for a specific purpose.

Common Security Zones

The following table lists common zones:

Zone	Description
Screened subnets	A screened subnet is used as a public-facing accessible network. It acts as a buffer and a barrier to your internal production network, which is accessible from the internet. A screened subnet can be configured using either one or two firewalls and acts as the middleman between the internet and your internal network. For example, a screened subnet is often used to allow employees access to critical network components, such as email servers, VPN connections, and internal web servers, from outside the company. Screened subnets are also used to provide customer access to a company's products, such as software. To do this, the firewall allows traffic from the internet into the screened subnet and enables those resources to access resources on the production network. The servers placed in the screened subnet are typically configured as a bastion host. A bastion host is a server that's specifically designed and configured to withstand attacks. In general, they are specific-purpose systems that host a single application and are hardened to resist attacks.
Intranet	An intranet is a private network (LAN) that employs internet information services for internal use only. For example, your company network might include web servers and email servers that are used by company employees.
Extranet	An extranet is a privately controlled network distinct from the intranet but located between the internet and a private LAN. An extranet is often used to grant resource access to business partners, suppliers, and even customers outside of the organization.
Wireless	A wireless zone is a broadcasted network connection used within an organization. Users do not need a physical connection to a network port to connect to the intranet or internal resources. Instead, they use a wireless connection on their device to connect to a wireless access point.

5.2.6 Configure Network Security Appliance Access (Demo Video)

Transcript:

In this demonstration, we're going to secureÂ access to our LAN and WAN interfaces and configure IP addresses to them. We're also going to work with user accounts on a network security appliance.Â We're using a pfSense securityÂ appliance, which has a graphical interface forÂ configuration that's accessible through a web browser.

I'm here at the login screen, and I'll sign in with the default username of â€˜admin'. For this pfSense device, the default password is â€˜pfsense'. I'll click Sign In to log on.
The first thing I want to do is configure the IP address on my WAN and my LAN. We'll start with the LAN settings. Go up to Interfaces > LAN, and that takes us to the LAN configuration page. If I look here, the IPv4 Configuration Type is set to Static IPv4. DHCP is the other option there. I need to change it to a different IP address. I want to change it to â€˜10.10.10.1', so I'll do that now. Now I want to confirm that my subnet is set to the /24 subnet mask. That's all I need to do on this page. I'll scroll down and click Save.
The page refreshes and says that the LAN configuration has changed, and I need to click Apply Changes for it to take effect. It reminds me to change my DHCP server configuration if needed. Since my IP address is in the same subnet range as it was before, my DHCP configuration is still okay. Just make sure the IP you assigned is not in the scope of IPs you've configured to be leased. Click Apply Changes.
Now, if you look up at my address, you'll see that it says 10.10.10.254. When I log back in, I need to go to the new address that I configured. I've found that you sometimes get a token error if you just try to log back in, so I'm going to close my web browser and open it back up.
Now let's type in '10.10.10.1' to get back to our Sign In page. I'll put my credentials back in here and click Sign In. I'll go back to my LAN interface, and you can see that my changes are there.
Now let's configure our WAN settings. Once again, I'll go to Interfaces. But this time, I'll select WAN from the list. Right now, I'm getting an IP for my WAN interface via DHCP. I want to configure this with a static IP, so I'll change that to Static IPv4 from our IPv4 configuration type.
Now, for an IP address, I'll give it â€˜192.168.25.254'. Right away, you might be saying, "Hey, that's a Class C Private IP address." If so, you're absolutely correct. I'm on a test network that's connected to my regular network, which is using the 192.168 scheme. I need to set my subnet mask to /24 here. For this demo, I'm not going to configure DHCP version 6. I'm going to leave everything else set to the defaults and click Save to continue.
I get a few reminders, just like we did with the LAN configuration. I'll click Apply Changes.
Now I want to configure the DNS that my WAN will use. A lot of devices will have those settings right here, with the WAN settings. But with this device, we need to go up to System > General Setup.
I'm going to add a few DNS servers here. But first, let's take a look at the current status of our WAN interface. To do that, I'll go to Status > Interfaces. Here, we see that my DNS server is using the home address of 127.0.0.1. IPv4 network standards reserve the entire address block 127.0.0.0/8 for loopback purposes, so this is normal. I want to change those to a different DNS, so let's go back to System > General Setup. Beneath DNS Server Settings, I'll put in the Google DNS IP of â€˜8.8.8.8'. Now I'll click the Add DNS Server button, and this time, I'll put in the other Google DNS IP of â€˜8.8.4.4'.
I'm going to check this box, Disable DNS Forwarder. For this demo, I don't want my local host, 127.0.0.1, to be used as my first DNS server. Checking the box will remove the local host DNS. I'm only doing this to demonstrate what happens when you check the box. I'll scroll down to save these settings.
Now let's look at the status of our interfaces. We can see our DNS settings are now set to the Google DNS servers. That wraps up configuring IP interfaces.
Now let's add an additional user to our pfSense appliance. To add a user, we need to go up to System > User Manager. You can see here that we have just one user, the admin user. It's good practice not to use the admin account for normal maintenance. You usually want to create a separate account for each person that might mange the device, collect logs, and so on. We can also track the logon and logoff events of the users in case something happens.
I'll add the user by going over and clicking the Add User button. I'll enter in a username of â€˜Rachel McGaffey'. I'll give Rachel a password, and I'll put the password in a second time to confirm it. Now, under Full Name, I'll enter in â€˜Rachel McGaffey'. That's really all that's required. But if I wanted to, I could check this box to customize the GUI for Rachel's account. Let's take a look at some of those options.
After I check the box, I get some more options. I can change the theme for her account from this dropdown list. We can change the top navigation of the page here. We can change how the hostname appears in the menu and change the

amount of dashboard columns. If we want things like WAN and LAN to be sorted alphabetically, we can change that too. If we have groups set up, we can change the memberships here. But we won't make any changes to these right now. Let's come down and click Save.
One thing we don't want to happen with our security appliance is have someone logged in to it make configuration changes. If a user gets called away from his or her desk and doesn't sign out, anyone can sit down at their computer and start messing around. To mitigate this risk, we want to configure Session Timeout. I'll click on the Settings tab. Under Session Timeout, I'm going to change this to 10 minutes. That is actually a long time, and you might want to set this to a lower amount of time. Having no timeout is a huge security risk. You'll have to judge your circumstances and decide what session timeout settings are best.
The last thing I want to do in this demo is change the default admin password. Default passwords for devices are easy to find with a simple web search. It's such a problem, some US states and other governments have forced many tech manufacturers to make the devices they produce have random passwords. Even if your device comes with a random password already configured, those passwords are often printed on the device somewhere, so it's always recommended that you change itâ€"that should be the very first thing you do.
To change this password for the admin account, I'll click on the edit icon here. I'll type in my new password. Now I'll type it a second time to confirm it. Come down and click Save, and that's all there is to it.
That's it for this demonstration.Â In this demo, we configured a network security appliance.Â We configured the LAN and WAN IP addresses. We changed the WAN DNS. We created a second account on the device. We configured a session timeout. We ended the demo by changing the defaultÂ admin password to something more secure.

5.2.7 Configure a Security Appliance (Simulation)

Scenario

You are an IT security administrator for a small corporate network. To increase security for the corporate network, you have installed the pfSense network security appliance in your network. Now you need to configure the device.

In this lab, your task is to configure pfSense as follows:

- Sign in to pfSense using the following case-sensitive information:
  - URL: **198.28.56.22**
  - Username: **admin**
  - Password: **P@ssw0rd**
- Configure the DNS servers as follows:
  - Primary DNS server: **163.128.78.93** - Hostname: **DNS1**
  - Secondary DNS server: **163.128.80.93** - Hostname: **DNS2**
- Configure the WAN IPv4 information as follows:
  - Enable the interface.
  - Use a static IPv4 address of **65.86.24.136/8**
  - Add a new gateway using the following information:
    - Type: **Default gateway**
    - Name: **WANGateway**
    - IP address: **65.86.1.1**

Explanation

Complete this lab as follows:

1. Access the pfSense management console.
   a. From the taskbar, select **Google Chrome** .
   b. Maximize the window for better viewing.
   c. In the address bar, type **198.28.56.22** and then press **Enter** .
   d. Sign in using the following case-sensitive information:
      - Username: **admin**

        - Password: **P@ssw0rd**
    e. Select **SIGN IN** or press **Enter** .
2. Configure the DNS Servers.
    a. From the pfSense menu bar, select **System** > **General Setup** .
    b. Under *DNS Server Settings* , configure the primary DNS Server as follows:
        - Address: **163.128.78.93**
        - Hostname: **DNS1**
        - Gateway: **None**
    c. Select **Add DNS Server** to add a secondary DNS Server and then configure it as follows:
        - Address: **163.128.80.93**
        - Hostname: **DNS2**
        - Gateway: **None**
    d. Scroll to the bottom and select **Save** .
3. Configure the WAN settings.
    a. From the pfSense menu bar, select **Interfaces** > **WAN** .
    b. Under General Configuration, ensure **Enable interface** is selected.
    c. Use the *IPv4 Configuration Type* drop-down to select **Static IPv4** .
    d. Under Static IPv4 Configuration, in the IPv4 Address field, enter **65.86.24.136** .
    e. Use the IPv4 Address subnet drop-down to select **8** .
    f. Under Static IPv4 Configuration, select **Add a new gateway** .
    g. Configure the gateway settings as follows:
        - Default: Select **Default gateway**
        - Gateway name: Enter **WANGateway**
        - Gateway IPv4: **65.86.1.1**
    h. Select **Add** .
    i. Scroll to the bottom and select **Save** .
    j. Select **Apply Changes** .

5.2.8 Configure Network Security Appliance Access (Simulation)

Scenario

You work as the IT security administrator for a small corporate network. You need to secure access to your pfSense appliance, which is still configured with the default user settings.

In this lab, your task is to:

- Change the password for the default pfSense account from P@ssw0rd to **1w0rm4b8.**
- Create a new administrative user with the following parameters:
    - Username: **zolsen**
    - Password: **St@yout!**
    - Full Name: **Zoey Olsen**
    - Group Membership: **admins**
- Set a session timeout of **15** minutes for pfSense.
- Disable the webConfigurator anti-lockout rule for HTTP.

Access the pfSense management console through Google Chrome using: **http://198.28.56.22**

- Default username: **admin**
- Password: **P@ssw0rd**

Explanation

Complete this lab as follows:

1. Access the pfSense management console.
    a. From the taskbar, select **Google Chrome** .
    b. Maximize the window for better viewing.
    c. In the Google Chrome address bar, enter **198.28.56.22** and then press **Enter** .
    d. Enter the pfSense sign-in information as follows:
        - Username: **admin**
        - Password: **P@ssw0rd**
    e. Select **SIGN IN** .
2. Change the password for the default (admin) account.
    a. From the pfSense menu bar, select **System > User Manager** .
    b. For the admin account, under Actions, select the ***Edit user*** icon (pencil).
    c. For the Password field, change to **1w0rm4b8** .
    d. For the Confirm Password field, enter **1w0rm4b8** .
    e. Scroll to the bottom and select **Save** .
3. Create and configure a new pfSense user.
    a. Select **Add** .
    b. For Username, enter **zolsen** .
    c. For the Password field, enter **St@yout!** .
    d. For the Confirm Password field, enter **St@yout!**
    e. For Full Name, enter **Zoey Olsen** .
    f. For Group Membership, select **admins** and then select **Move to Member of list** .
    g. Scroll to the bottom and select **Save** .
4. Set a session timeout for pfSense.
    a. Under the *System* breadcrumb, select **Settings** .
    b. For Session timeout, enter **15** .
    c. Select **Save** .
5. Disable the webConfigurator anti-lockout rule for HTTP.
    a. From the pfSense menu bar, select **System** > **Advanced** .
    b. Under webConfigurator, for Protocol, select **HTTP** .
    c. Select **Anti-lockout** to disable the webConfigurator anti-lockout rule.
    d. Scroll to the bottom and select **Save** .

5.2.9 Deceptive and Disruption Technology (Lesson Video)

Transcript:

In this lesson we'll discuss attack deceptions. By now you should have a clear understanding of what an attack is and what it looks like. Threat agents are working hard to find weaknesses in your defenses. They will exploit any vulnerability to gather information from an organization's network system.

Knowing this, organizations can set up data or add devices to their networks that lures unsuspecting attackers into attacking devices. The attacking devices are designed to trap attackers and prevent them from exfiltrating any useful information.
The first item we'll look at is the honeypot. As the name implies, if you look inside, you'll find will find something sweet. A honeypot is a network set up to fool an attacker into thinking he's attacking a network device critical to your company; however, it's simply a ruse. The attacker can attack the honeypot as long as he wants and get as deep as he wants; however, there is no prize or honey in the end.
A honeypot can be a host, a service on a host, a network device, a virtual entity, or even a single file set up to attract attackers to a secure area away from an organization's real network. Even better, while it's distracting the attacker, you can monitor the malicious activity to learn what the attacker is trying to do.
For example, if an attacker attempts an exploit or upload a rootkit or Trojan to a server, the honeypot environment will safely store those files for malware collection and analysis.

There are several types of honeypots that are designed to mimic and trap different types of attacks. Each honeypot falls into one of two categories: research or production. Research honeypots are typically used by research, military, or government organizations to gather information about the motives and tactics of the attackers. They are also used for educational purposes. Production honeypots are used, primarily by private and public organizations.

Let's look at a few examples of production honeypots.

First, you have the SSH honeypots. SSH honeypots are designed to trap brute force attacks that attempt to guess the password of a targeted device. Perhaps more importantly, this type of honeypot captures the complete shell history performed by the attacker. Next, we have HTTP honeypots. This type of honeypot is used to trap different types of web vulnerabilities such as SQL injections, file insertions, and web application attacks.

We also have WordPress honeypots which are designed to attract spam and adware attacks. An email honeypot is used to attract SMTP-based attacks such as open relay, DDoS, and spam attacks. And lastly, there are several types of honeypots designed for TCP/IP-based protocol attacks.

To make things more enticing to the attackers, many companies will create a decoy network and fill it with one or more honeypots. This is known as a honeynet. The information gained from a honeynet attack serves to strengthen an organization's defense against future attack.

Similar in concept to a honeypot, a honeyfile is a single file setup to entice and trap attackers and to figure out what they're trying to do. These types of files are typically set up on a file server, and when accessed, an alarm is set off notifying that administrators of the attack. These types of alarms are often sent by email directly to the user, which can also be easily seen on a phone and almost instantly interpreted. Honeyfiles are named so the hacker will try and open or execute them. For example, files with names such as passwords.txt or IP Assignments.xls are prized targets for hackers to gain useful information about a user or system.

When it comes to honeyfiles, attackers are typically interested in four types of files. First, are the informational files. These are the types of files that contain information about access other systems, like a password.txt file, and security files like Microsoft word file named vpn_instructions. The second type are application or program files that an attacker may run, but the normal user wouldn't, such as a complier. Third, hackers love to attack files that contain evidence of an attack such as log files. The last type of file commonly targeted by attackers are files that might contain intellectual property such as a forecast, credit card numbers, and product roadmaps.

As you can see, honeyfiles protect a wide variety of files and systems including email and email attachments. Although we've pointed out the four major types of file that attack hackers, keep in mind that any file can be used as a honeyfile. Honeyfiles also work with network intrusion detection systems, or NIDS, and help to prevent false positives.

The other nice thing about honeyfiles is that if end users are properly trained, they can create their own honeyfiles and set up their own alarms and alerts. Enabling users makes the detection process easy and deployment effectiveness is high.

Since users create their own honeyfiles, they receive the alarm if they accidentally access one of their own monitored files. This virtually eliminates false positives that have be investigated. This saves time, effort, and energy for system management charged with keeping the network secure. Further, this process supports a defense-in-depth strategy.

Now let's shift gears and discuss DNS sinkholes.

Simply put, a DNS sinkhole is used to provide false information for DNS queries. Although this may sound counterintuitive, providing false information can help to prevent a denial-of-service or distributed denial-of-service attack. DNS sinkholes are an effective measure that blocks malicious traffic and blocks bots from successfully taking a site down using a DDoS attack.

It's important to understand that a DNS sinkhole is not a product. Instead, it's a method used by system management to fool an attacker by providing bogus information. For example, suppose a bot attempts to use DNS to forward information. The DNS server returns fake information and the bot can't continue its malicious activity. As another example, supposed an attacker sends a malicious email to an unsuspecting user. Should the user click the link in the email, the DNS sinkhole would prevent the attack by resolving the DNS query to a false site.

Creating a DNS sinkhole is not without its limitations. To work correctly, the malware must use the organization's DNS server. If it uses a public DNS server or its own DNS server, this won't work. You can mitigate this by configuring firewalls to block DNS queries going outside the perimeter.

It's also important to understand that a sinkhole doesn't prevent malware and can't prevent malware execution or remove malware from the system. However, the DNS server will be configured with potential malware sites.

Creating a sinkhole can take time. Even if obtained from trusted internet sources, its possible legitimate sites are used to forward malicious content. This could result in restrictions to legitimate websites. Therefore, sinkholes should be internal only. If attackers can access the DNS server externally, they can change entries in the sinkhole and use it to their benefit.

While many threat agents are looking for open and available vulnerabilities, others are looking to infiltrate a network's defenses and either copy intellectual property or damage internal systems. It's truly a cat and mouse game played by

attackers and network managers. Attackers are always trying new techniques to perform their reconnaissance and discover weakness they can exploit. One method used by system managers is the concept of fake telemetry. Telemetry is defined as the collection of data at remote points and their automatic transmission to receiving equipment for monitoring. As such, organizations provide false data, meant to deceive the attacker. This type of fake information might include fake credentials or fake IP address information. It might be an internal report detailing vulnerable systems that require updates when, they are really honeypots designed to capture attacker information.

The primary reason for providing fake information is to get the attacker to act on the false information. Since the information is controlled by system managers, they can utilize alerts, alarms, and logs to track the techniques and tools used by an attacker. The tracked information allows system management to tune perimeter equipment such as firewalls, NIDS, NIPS and other protections.

That's it for this lesson. In this video, we discussed deception techniques used by companies to protect themselves from attackers. We discussed such techniques as using honeypots, honeyfiles, and honeynets to lure attackers into fake areas. We also discussed the benefits of using DNS sinkholes. And we ended this lesson outlining the benefits of companies using fake telemetry.

5.2.10 Deceptive and Disruption Technology Facts

Deception and disruption technologies are cybersecurity resilience tools and techniques used to increase the cost of attack planning for the threat actor.

This lesson covers the following topics:

- Honeypots
- Honeynets and honeyfiles
- DNS sinkholes
- Fake telemetry

Honeypots

Honeypots are decoy systems that mimic real systems and applications. They are designed to allow security teams to monitor attacker activity and gather information about their tactics and tools. A honeypot can be a host, a service on a host, a network device, a virtual entity, or even a single file set up to attract attackers to a secure area away from an organization's real network. Even better, while it is distracting the attacker, you can monitor the malicious activity to learn what the attacker is trying to do.

There are several types of honeypots that are designed to mimic and trap different types of attacks. Each honeypot falls into one of two categories: research or production. Research honeypots are typically used by research, military, or government organizations to gather information about the motives and tactics of the attackers. They are also used for educational purposes. Production honeypots are used primarily by private and public organizations. Examples include the following:

- SSH honeypots — SSH honeypots are designed to trap brute force attacks that attempt to guess the password of a targeted device. Perhaps more importantly, this type of honeypot captures the complete shell history performed by the attacker.
- HTTP honeypots — HTTP honeypots are used to trap different types of web vulnerabilities, such as SQL injections, file insertions, and web application attacks.
- WordPress honeypots — WordPress honeypots are designed to attract spam and adware attacks.
- Email honeypots — Email honeypots are used to attract SMTP-based attacks such as open relay, DDoS, and spam attacks.
- Various other honeypots designed for TCP/IP-based protocol attacks.

Honeynets and Honeyfiles

To make things more enticing to the attackers, many companies will create a decoy network and fill it with one or more honeypots. This is known as a honeynet. The information gained from a honeynet attack serves to strengthen an organization's defense against future attacks.

A honeyfile is a single file setup to entice and trap attackers and to figure out what they are trying to do. These types of files are typically set up on a file server, and when accessed, an alarm is set off, notifying administrators of the attack. These types of alarms are often sent by email directly to the user, which can also be easily seen on a phone and almost instantly interpreted.

Honeyfiles are named so the hacker will try and open or execute them. For example, files with names such as passwords.txt or IP Assignments.xls are prized targets for hackers to gain useful information about a user or system. Four of the most common types of files used to attract an attacker include the following:

- Information files — These are the types of files that contain information about accessing other systems, like a password.txt file, and security files, like a Microsoft Word file named vpn_instructions.
- Application or program files — These are files that a normal user would not run but an attacker might, such as a compiler.
- Log files — An attacker may be attracted to log files, thinking they might contain evidence of an attack or other helpful information.
- Intellectual property files containing information such as forecasts, credit card numbers, and product roadmaps.

Keep in mind the following facts about honeyfiles:

- Any file can be used as a honeyfile.
- Honeyfiles work with network intrusion detection systems (NIDs) and can help prevent false positives.
- If end users are properly trained, they can create their own honeyfiles with their own alarms and alerts.
    - This makes the detection process easy and deployment effectiveness high.
    - Since users create their own honeyfiles, they receive the alarm if they accidentally access one of their own monitored files.
        - This virtually eliminates false positives that have to be investigated.
        - This saves time, effort, and energy for system management charged with keeping the network secure.
        - This process supports a defense-in-depth strategy.

Honeytokens are false credentials, login credentials, or other data types used to distract attackers, trigger alerts, and provide insight into attacker activity.

By deploying honeypots, honeynets, honeyfiles, or honeytokens, organizations can detect and monitor attacks, gather intelligence about attackers and their methods, and proactively defend against future attacks. These tools can also provide an additional layer of defense by diverting attackers' attention away from real systems and applications, reducing the risk of successful attacks.

DNS Sinkhole

A DNS sinkhole is a temporary DNS record that redirects malicious traffic to a controlled IP address. Simply put, a DNS sinkhole is used to provide false information for DNS queries. Providing false information can help to prevent a denial-of-service or distributed denial-of-service attack. DNS sinkholes are also an effective measure that blocks malicious traffic and blocks bots from successfully taking a site down using a DDoS attack.

Creating a DNS sinkhole is not without its limitations. To work correctly, the malware must use the organization's DNS server. If it uses a public DNS server or its own DNS server, this will not work. You can mitigate this by configuring firewalls to block DNS queries going outside the perimeter. A sinkhole does not prevent malware and cannot prevent malware execution or remove malware from the system.

Creating a sinkhole can take time. Even if obtained from trusted internet sources, it's possible legitimate sites are used to forward malicious content. This could result in restrictions to legitimate websites. Therefore, sinkholes should be internal only. If attackers can access the DNS server externally, they can change entries in the sinkhole and use it to their benefit.

Fake Telemetry

Fake telemetry is a deception strategy that returns spoofed data in response to network probes. Telemetry is defined as the collection of data at remote points and their automatic transmission to receiving equipment for monitoring. As such, organizations provide false data meant to deceive the attacker. This type of fake information might include fake credentials or fake IP address information. It might be an internal report detailing vulnerable systems that require updates when they are really honeypots designed to capture attacker information.

The primary reason for providing fake information is to get the attacker to act on the false information. Since the information is controlled by system managers, they can utilize alerts, alarms, and logs to track the techniques and tools used by an attacker. The tracked information allows system management to tune perimeter equipment such as firewalls, NIDS, NIPS, and other protections.

5.2.11 Detect Malicious Network Traffic with a Honeypot (Demo Video)

Transcript:

Reconnaissance tools like nmap can find vulnerable systems on the internet. These tools scan ranges of IP addresses for systems with interesting ports open, such as Telnet, Remote Desktop, SSH, and FTP. Many ethical hackers like to know who's gathering this kind of information, and there's a simple way to record reconnaissance attempts. In order to record these network scans, we need a computer whose sole purpose is to listen for connection attempts on interesting ports, then log the data about each attempt. This kind of system is called a honeypot. It looks appealing and hackable from the outside, but it's actually recording data about every remote user that attempts to connect. Today, we'll look at how to set up an extremely basic honeypot using a tool called Pentbox.

Pentbox is available online, but many people upload copies of the original program. When downloading tools, especially hacking tools, you have to be certain of the tool's integrity so you don't download malicious software. I've already downloaded the tool and put it in a folder named pentbox, so let's open that now. From my Kali Linux machine, I'll open a terminal and navigate to 'cd pentbox/'. I'll list the folder's contents to make sure everything is there.
Pentbox is a Ruby script. Since Ruby is already installed on Kali, we just need to run the script. To do that, I'll type './pentbox.rb' and press Enter.
When it opens, we can see a variety of options. Pentbox does a lot of things. But right now, we're only interested in the honeypot utility, which is located under Network Tools. First, I'll select number 2, and then we'll select Honeypot, number 3.
After we've selected the Honeypot utility, we're presented with the option to use either fast or manual configuration. I'm going to select number 1, the Fast Autoconfiguration option, since the manual configuration only lets us change which port the tool listens on. It also lets us set the message to return to the requesting machine.
As soon as we press Enter, we're told that the honeypot has started running on port 80. Let's try connecting to it with Firefox to see what happens. I'll open Firefox and type 'localhost' in the address bar. We can see that the honeypot returns back a web page that tells us access has been denied. Interestingly, the autoconfiguration option returns a line with a date and time. This doesn't change; actually, it represents the time the tool was started. Now that we've connected to the page, let's see what Pentbox says.
Okay, I'm back on my Kali Linux system. It looks like the honeypot utility is telling us quite a bit of information. The first line of each entry shows that there was a connection attempt and tells us what the IP address of the connecting machine was, as well as the connection time. After that, the honeypot utility tells us the header information that was received when the connection was made. This information includes both the web browser that was used and information about the type of operating system that connected.
So, there's a really simple overview of a honeypot's function. This is just a taste of what you can accomplish- there are many more robust tools available that can log information about connections on many different ports and protocols simultaneously, which is a goldmine of data that will help you keep your network safe.

5.2.12 Configure Load Balancer (Demo Video)

Transcript:

A load balancer can be either a software or a hardware appliance that distributes the load across multiple servers using TCP or UDP. Some examples could include websites, web services, email, print servers, and much more. Not only can it serve the purpose of load balancing, but it can also be used for failover. Today, we're going to be using a software load balancer called Kemp. This is an easy-to-install software load balancer deployed to VMware with an .ovf template.

One of the first things you must do is configure a Virtual Service. The virtual service will have an IP address associated with it. This is simply the IP address that users will connect to instead of the real server addresses where load balancing occurs. Our Virtual Address will be 192.168.30.31, which is outside our DHCP zone. Port 80 will be used since this is just an HTTP website. We can also add a Service Name so we know what this is for. Templates are useful because they help predefine some settings related to the type of service you're load balancing. These can be obtained from Kemp's website, as you can see here. This example shows Apache and Tomcat templates, but as we scroll up, there are many different types of services that we can load balance with Kemp. Let's go back to our load balancer. We'll select the Apache HTTP template and then click Add this Virtual Service. When this service is added, there are several options available, such as quality of service or limiting. These options can help ensure that the service you're load balancing isn't overloaded. The default is 0, which means off. Advanced settings can also assist with tasks such as redirecting or enabling caching.
At the bottom is where we'll add our real servers. These are the actual web servers that we'll be load balancing. When we click Add New, we'll input our first web server, 192.168.30.10, and then click Add This Real Server. Our second one will be 192.168.30.11. Both web servers will use port 80 since they're serving only HTTP websites. The Forwarding method will remain as NAT since that's the only option. The Weight can be adjusted if you want to send more traffic to one server over the other. For now, we've left them both at 1000. One useful feature is that when you hover over these options, it provides a description to help you configure them. Connection Limit and Connection Rate Limit can be set, but we won't be doing that today. Click Add This Real Server. After clicking OK, you can see that we have two real servers now configured for this virtual service.
We need to make some more changes for this virtual service to work correctly. If we go to View/Modify Services, we can see the virtual service we've created. Clicking Modify on the right will allow us to go back into the settings. Down at the bottom, we need to set the URL we're looking to load balance. Since our web servers don't have a website at the root directory, we need to add /test.html to the URL area. Next, click Set URL.
Now, we're ready to test out load balancing with our websites. If we open a new tab, we can go to http://192.168.30.10/test.html. This will show us our first web server, and if we modify the address and change the 10 to 11, we'll access our second web server. In a real-world scenario, the websites on both servers would be identical; however, we've made them different so you can tell which server you're on during load balancing. Now that we know our web servers work, let's use our virtual IP address. If we go back to our load balancer, it can detect that both web servers are online. Our virtual IP will be 192.168.30.31. Let's go there. When we type it in, you can see that it's directing us to webserver-svp01.
A common thing we can do with a virtual IP is associate it with a DNS name. On our Pi-hole DNS server, we can scroll down and go to Local DNS and DNS Records. You can already see that we have records for our web servers, so let's add a record for our virtual IP. The domain will be testwebsite.com, and our virtual IP address is 192.168.30.31. After clicking Add, it will add it to the list of records. Let's test this out. In our web tab, we'll remove the IP address and enter testwebsite.com, then click Enter. Great, it still shows webserver-svp01.
To make things more interesting, let's force traffic to go to webserver-svp02 since we have maintenance to attend to on webserver-svp01. If we go back to our load balancer tab and Modify our virtual service, we can go down to our real servers and click Disable on webserver-svp01. Once this is disabled, we can go back and test. Please note that many browsers cache websites, so in order for this change to be visible right away, we must open a new private browsing window. Now, if we enter our web address testwebsite.com/test.html, we can see that it's now showing webserver-svp02.
That's it for this demo. In this demo, we showed you how to configure a load balancer, add web servers to the load balancer, and test both IP and DNS with our web servers.

5.2.13 Practice Questions (Section Quiz)

q_sec_sol_appliance_secp8

You are the office manager of a small financial credit business. Your company handles personal financial information for clients seeking small loans over the internet. You are aware of your obligation to secure clients records, but the budget is an issue for your company.

Which item would provide the BEST security for this situation?

Answers:

- Network access control system
- Proxy server with access controls
- ***All-in-one security appliance**
- Firewall on your gateway server to the internet

Explanation:

An all-in-one security appliance would provide the best overall protection. All-in-one security appliances take up the least amount of space and require the least amount of technical assistance for setup and maintenance.

Security functions in an all-in-one security appliance can include the following:

- Spam filter
- URL filter
- Web content filter
- Malware inspection
- Intrusion detection system (IDS)

In addition to security functions, all-in-one security appliances can include the following:

- Network switch
- Router
- Firewall
- Tx uplink (integrated CSU/DSU)
- Bandwidth shaping

q_sec_sol_block_rules_secp8

A technician is deploying centralized web filtering techniques across the enterprise.

What stems from various factors such as the website's URL, domain, IP address, content category, or even specific keywords within the web content?

Answers:

- ***Block rules**
- Reputation-based filtering
- URL scanning
- Content categorization

Explanation:

Block rules stem from various factors such as the website's Uniform Resource Locators (URL), domain, Internet Protocol (IP) address, content category, or even specific keywords within the web content.

Reputation-based filtering leverages continually updated databases that score websites based on their observed behavior and history.

URL scanning is a method that protects web traffic as the proxy server examines the URLs requested by users and can block access to specific URLs known to host malicious content, are inappropriate, or violate the company's Internet usage policy.

Content categorization classifies websites into various categories, such as social networking, gambling, adult content, webmail, and many others.

q_sec_sol_content_01_secp8

You are implementing security at a local high school that is concerned with students accessing inappropriate material on the internet from the library's computers. The students use the computers to search the internet for research paper content. The school budget is limited.

Which content filtering option would you choose?

Answers:

- Block all content except for content you have identified as permissible.
- ***Restrict content based on content categories.**
- Block specific DNS domain names.
- Allow all content except for the content you have identified as restricted.

Explanation:

Restricting content based on categories would provide the most protection with the least amount of research and involvement.

All other options require research to identify specific content or websites, which could allow access to undesirable websites or prevent access to necessary websites.

q_sec_sol_content_02_secp8

A cyber group is reviewing its web filtering capabilities after a recent breach.

Which centralized web-filtering technique groups websites into categories such as social networking, gambling, and webmail?

Answers:

- ***Content categorization**
- Block rules
- Reputation-based filtering
- URL scanning

Explanation:

Content categorization classifies websites into categories such as social networking, gambling, adult content, webmail, and many others.

Block rules stem from various factors such as the website's Uniform Resource Locators (URL), domain, Internet Protocol (IP) address, content category, or even specific keywords within the web content.

Reputation-based filtering leverages continually updated databases that score websites based on their observed behavior and history.

URL scanning is a method that protects web traffic as the proxy server examines the URLs requested by users and can block access to specific URLs known to host malicious content, are inappropriate, or violate the company's internet usage policy.

q_sec_sol_fail_closed_open_secp8

Which of the following descriptions is true about fail-open and fail-closed configurations for security devices in the event of a failure?

Answers:

- Fail-open prioritizes confidentiality and integrity over availability, while fail-closed prioritizes availability over confidentiality and integrity.
- Fail-open means that access is blocked or that the system enters the most secure state available, while fail-closed means that network or host access is preserved, if possible.
- ***Fail-open means that network or host access is preserved, if possible, while fail-closed means that access is blocked or that the system enters the most secure state available.**
- Both fail-open and fail-closed prioritize confidentiality and integrity over availability.

Explanation:

In a fail-open configuration, the system maintains network or host access, if possible, in the event of a failure. In a fail-closed configuration, the system blocks access or enters the most secure state available in the event of a failure.

Fail-open prioritizes availability over confidentiality and integrity, while fail-closed prioritizes confidentiality and integrity over availability.

Fail-open means preservation of network or host access, if possible, while fail-closed means blocked access or the system entering the most secure state available.

q_sec_sol_fail_closed_secp8

You have configured a security device in your network to fail-closed.

Which of the following will happen when an attack occurs?

Answers:

- The device will preserve network or host access when it fails.
- ***The device will block access or enter the most secure state available when it fails.**
- The device will distribute network traffic across multiple servers when it fails.
- The device will act on behalf of a client when accessing resources over the internet when it fails.

Explanation:

In a fail-closed configuration, the system prioritizes confidentiality and integrity over availability. If a failure occurs, access is blocked or the system enters the most secure state available.

Preserving network or host access when the device fails describes a fail-open configuration, not fail-closed. In a fail-open scenario, the system prioritizes availability over confidentiality and integrity.

Distributing network traffic across multiple servers when the device fails describes the function of a load balancer, not a fail-closed configuration. A device configured to fail-closed will not distribute network traffic across multiple servers when it fails.

Acting on behalf of a client when accessing resources over the internet when the device fails describes the function of a proxy server, not a fail-closed configuration. A device configured to fail-closed will not act on behalf of a client when accessing resources over the internet when it fails.

q_sec_sol_load_balancer_secp8

What is the main role of a load balancer in network security?

Answers:

- ***To distribute network traffic across multiple servers.**
- To act as a gateway to access certain isolated systems.
- To capture packets for intrusion detection.
- To act on behalf of a client when accessing resources over the internet.

Explanation:

A load balancer distributes client requests across available server nodes in a farm or pool, optimizing performance and providing fault tolerance.

To act as a gateway to access certain isolated systems is the function of a jump server, not a load balancer.

To capture packets for intrusion detection is the purpose of a sensor, not a load balancer.

To act on behalf of a client when accessing resources over the internet is the function of a proxy server, not a load balancer.

q_sec_sol_proxy_01_secp8

A proxy server can be configured to do which of the following?

Answers:

- ***Restrict users on the inside of a network from getting out to the internet.**
- Allow all content except for the content you have identified as restricted.
- Block all content except for the content you have identified as permissible.
- Act as a unified threat security device or web security gateway.

Explanation:

Proxies can be configured to:

- Restrict users on the inside of a network from getting out to the internet.
- Restrict access by user or by specific website.
- Restrict users from using certain protocols.
- Use access controls to control inbound or outbound traffic.

- Shield or hide a private network to provide online anonymity and make it more difficult to track web surfing behavior.
- Cache heavily accessed web content to improve performance.

An internet content filter is software used to monitor and restrict content delivered across the web to an end user. Two types of configurations are commonly used, which are:

- Allow all content except for the content you have identified as restricted.
- Block all content except for the content you have identified as permissible.

All-in-one security appliances combine many security functions into a single device. All-in-one security appliances are also known as unified threat security devices or web security gateways.

q_sec_sol_web_filter_01_secp8

An organization needs to implement web filtering to bolster its security. The goal is to ensure consistent policy enforcement for both in-office and remote workers.

Which of the following web filtering methods BEST meets this requirement?

Answers:

- ***Deploying agent-based web filtering**
- Utilizing a centralized proxy server
- Implementing manual URL blocking
- Relying solely on reputation-based filtering

Explanation:

Agent-based web filtering involves installing a software agent on all devices. These agents communicate with a centralized server to obtain filtering policies and rules and apply them locally.

While a centralized proxy server effectively controls and monitors all inbound and outbound web content, it may struggle to enforce policies when employees cannot connect from the corporate network, such as when working remotely or traveling.

Manual URL blocking as a primary method is impractical, given the sheer volume of potentially harmful websites and the rapid development and creation of new websites.

Although reputation-based filtering is an effective technique and is part of a comprehensive web filtering strategy, solely relying on it would not provide all-around protection.

q_sec_sol_web_filter_02_secp8

An organization needs a solution for controlling and monitoring all inbound and outbound web content, analyzing web requests, blocking access based on various criteria, and offering detailed logging and reporting of web activity.

Which of the following solutions is the MOST suitable in this situation?

Answers:

- ***Centralized web filtering**
- Agent-based filtering

- Manual URL blocking
- Content categorization

Explanation:

Implemented typically through a proxy server, centralized web filtering controls and monitors all inbound and outbound web content. It can analyze web requests and block access based on Uniform Resource Locators (URLs), Internet Protocol (IP) addresses, content categories, or specific keywords.

Agent-based filtering provides detailed logging and can block access based on established policies but does not control and monitor all inbound and outbound web content at the network level.

Manual URL blocking isn't the most effective solution to control and monitor all inbound and outbound web content.

Content categorization as a standalone feature does not provide comprehensive control, monitoring, and logging of all web content.

q_sec_zone_ad_hoc_secp8

Which of the following BEST describes an ad hoc network?

Answers:

- A network that requires a physical connection to a router or switch.
- A network that is designed to trap potential attackers.
- ***A network that is decentralized and allows connections without a traditional base station or router.**
- A network that grants internet access only for guest users.

Explanation:

An ad hoc network is a decentralized network that allows devices to connect directly to each other without the need for a traditional base station or router. This type of network is often used for a specific purpose, such as a temporary connection for a meeting or event.

An ad hoc network does not require a physical connection to a router or switch. Instead, it allows devices to connect directly to each other.

A honeynet is designed to trap potential attackers, not to allow direct connections between devices.

A guest network typically provides internet access to visitors, but it does not allow direct connections between devices without a router or switch.

q_sec_zone_extranet_secp8

Which of the following is a privately controlled portion of a network that is accessible to some specific external entities?

Answers:

- ***Extranet**
- Intranet
- Internet
- MAN

Explanation:

An extranet is a privately controlled portion of a network that is accessible to some specific external entities. Often, those external entities are business partners, suppliers, distributors, vendors, or customers.

An intranet is a LAN that employs the technology of the internet (namely, TCP/IP, web servers, and email).

The internet is the global TCP/IP-based network that supports most web and email communications.

A metropolitan area network (MAN) is a LAN that is spread across several city blocks, across a business park, or across a campus.

q_sec_zone_honeynet_secp8

You want to create a collection of computers on your network that appear to have valuable data but actually store fake data that could entice a potential intruder. Once the intruder connects, you want to be able to observe and gather information about the attacker's methods.

Which feature should you implement?

Answers:

- ***Honeynet**
- NIDS
- NIPS
- Extranet

Explanation:

A honeypot is a device or virtual machine that entices intruders by displaying a vulnerable trait or flaw or by appearing to contain valuable data. A honeynet is a network of honeypots.

A network-based IDS (NIDS) is a dedicated device installed on a network that's used to analyze all traffic on the network. An NIPS is a network-based intrusion prevention system that can take actions in response to intrusion.

An extranet is a privately controlled network located between the internet and a private LAN, but distinct from both. An extranet is often used to grant resource access to business partners, suppliers, and even customers outside of the organization.

q_sec_zone_intranet_secp8

A company wants to set up a private network that employs internet information services for internal use only, including web servers and email servers that are used by company employees.

What type of network is the company planning to set up?

Answers:

- Extranet
- Internet
- ***Intranet**
- Honeynet

Explanation:

An intranet is a private network (LAN) that employs internet information services for internal use only. For example, a company network might include web servers and email servers that are used by company employees. This matches the scenario described in the question.

An extranet is a privately controlled network distinct from the intranet but located between the internet and a private LAN. An extranet is often used to grant resource access to business partners, suppliers, and even customers outside of the organization. This does not match the scenario where the company wants a network for internal use only.

The internet is a public network that includes all publicly available web servers, FTP servers, and other services. The internet is public because access is largely open to everyone. This does not match the scenario where the company wants a private network for internal use only.

A honeynet is a special network created to trap potential attackers. Honeynets have vulnerabilities that lure attacks so that you can track their actions and protect your real network. This does not match the scenario where the company wants a network for internal use only.

q_sec_zone_screened_subnet_secp8

You are a network security engineer for a large corporation. The company is planning to launch a new software product and wants to provide customer access to this product over the internet.

The company also wants to ensure that the internal production network remains secure.

Which type of common security zone would be the MOST appropriate to implement in this scenario?

Answers:

- Intranet
- Extranet
- ***Screened Subnet**
- Wireless

Explanation:

Screened subnet is the correct answer. A screened subnet is used as a public-facing accessible network. It acts as a buffer and a barrier to the internal production network, which is accessible from the internet. It can be configured using either one or two firewalls and acts as the middleman between the internet and the internal network. This makes it the most appropriate choice for this scenario.

Intranet is incorrect because an intranet is a private network that is used for internal purposes only. It would not be appropriate for providing customer access to a product over the internet.

Extranet is incorrect because an extranet is used to grant resource access to business partners, suppliers, and even customers outside of the organization. However, it is not specifically designed to act as a buffer between the internet and the internal network, which is a requirement in this scenario.

Wireless is incorrect because a wireless zone is a broadcasted network connection used within an organization. It would not be appropriate for providing customer access to a product over the internet while also protecting the internal network.

q_attk_deception_dns_sinkhole_secp8

Which of the following is a limitation of using a DNS sinkhole as a cybersecurity measure?

Answers:

- DNS sinkholes can only provide false information for DNS queries.
- ***DNS sinkholes are ineffective if the malware uses a public DNS server or its own DNS server.**
- DNS sinkholes can block all types of malicious traffic.
- DNS sinkholes can prevent malware execution.

Explanation:

If the malware uses a public DNS server or its own DNS server, a DNS sinkhole will not be effective because it won't be able to intercept and redirect the DNS queries.

Providing false information for DNS queries is not a limitation but a function of DNS sinkholes.

While DNS sinkholes can block a lot of malicious traffic by redirecting it, they may not be able to block all types of malicious traffic, especially if the malware uses a different DNS server.

DNS sinkholes do not have the capability to prevent malware execution. They are used to redirect malicious traffic, not to stop malware from executing.

q_attk_deception_email_honeypot_secp8

You are the cybersecurity lead at a large corporation. Recently, your organization has been experiencing an increase in SMTP-based attacks such as open relay, DDoS, and spam attacks. You need to devise a strategy to not only mitigate these attacks but also gather information about the attackers' tactics.

Which of the following would be the BEST solution?

Answers:

- Implement a strong firewall and block all SMTP traffic.
- ***Set up an email honeypot designed to attract and trap these types of attacks.**
- Regularly change the email server's IP address to confuse the attackers.
- Shut down the email server until the attacks cease.

Explanation:

In this scenario, an email honeypot is the best solution. It is designed to attract SMTP-based attacks. While it's distracting the attacker, the cybersecurity team can monitor the malicious activity to learn what the attacker is trying to do, which can be used to strengthen the company's defenses.

While implementing a strong firewall is a good security measure, blocking all SMTP traffic would disrupt legitimate email communication, which is not practical for a large corporation.

Regularly changing the email server's IP address would likely cause significant disruption to legitimate email communication and may not effectively deter determined attackers.

Shutting down the email server would disrupt all email communication, which is not practical for a large corporation. Moreover, it does not provide any opportunity to learn about the attackers' tactics.

q_attk_deception_fake_telemetry_secp8

You are a cybersecurity specialist and you have implemented fake telemetry as part of your organization's defense strategy. An attacker has just probed your network.

Which of the following type of information might your fake telemetry system provide to the attacker?

Answers:

- Login credentials of your organization's employees.
- IP address information of your organization's servers.
- ***False credentials or false IP address information.**
- Credit card information of your organization's customers.

Explanation:

Fake telemetry provides false or spoofed data, such as fake credentials or fake IP address information, in response to network probes.

Providing real login credentials of your organization's employees would compromise the security of your organization, not enhance it.

Providing real IP address information of your organization's servers would expose your organization's network infrastructure to the attacker.

Providing real credit card information of your organization's customers would lead to a serious data breach and is not a function of fake telemetry.

q_attk_deception_honeyfiles_secp8

Which of the following statements about honeyfiles are true? (Select two.)

Answers:

- Honeyfiles are designed to provide real data to the attacker.
- ***Honeyfiles are named in a way that makes them attractive to hackers, enticing them to open or execute them.**
- ***Honeyfiles work with network intrusion detection systems (NIDs) and can help prevent false positives.**
- Honeyfiles are used to block all types of malicious traffic.
- Honeyfiles can only be created by system administrators.

Explanation:

The following are true statements about honeyfiles:

- Honeyfiles are named in a way that makes them attractive to hackers, enticing them to open or execute them.
- Honeyfiles work with network intrusion detection systems (NIDs) and can help prevent false positives by providing a controlled environment for detecting malicious activity.

Honeyfiles do not provide real data to the attacker. They are decoy files set up to attract and trap attackers.

While honeyfiles can help detect and track malicious activity, they do not directly block malicious traffic.

While system administrators often create honeyfiles, end users who are properly trained can also create their own honeyfiles with their own alarms and alerts.

q_attk_deception_honeynet_secp8

You are a cybersecurity specialist at a large corporation. Your company has been experiencing an increase in cyber attacks recently. To better understand the tactics and techniques of the attackers, you have decided to set up a honeynet.

Which of the following is the BEST way to set up and use a honeynet?

Answers:

- Set up the honeynet with real data and systems to make it more attractive to attackers.
- ***Set up the honeynet with decoy systems and monitor it for attacker activity.**
- Set up the honeynet with decoy systems and ignore it until an attack occurs.
- Set up the honeynet with real systems and ignore it until an attack occurs.

Explanation:

A honeynet should be set up with decoy systems that mimic real systems. Monitoring the honeynet allows the cybersecurity team to gather information about the attackers' tactics and tools, which can be used to strengthen the company's defenses.

Using real data and systems in a honeynet is incorrect as it could lead to real data breaches and system compromises. The purpose of a honeynet is to attract attackers with decoy systems, not real ones.

Simply setting up a honeynet and ignoring it until an attack occurs is incorrect because it does not take full advantage of the honeynet's potential. Monitoring the honeynet allows for the collection of valuable information about the attackers.

Using real systems in a honeynet is incorrect because it could lead to real system compromises. The purpose of a honeynet is to attract attackers with decoy systems, not real ones. Additionally, ignoring the honeynet until an attack occurs does not allow for the proactive gathering of information about the attackers.

5.3 Screened Subnets

As you study this section, answer the following questions:

- How is a honeypot used to increase network security?
- What is the typical configuration for a screened subnet?
- What is the function of each firewall in a two-firewall screened subnet?
- What type of computer might exist inside a screened subnet?
- What makes bastion hosts vulnerable to attack? How can you harden bastion hosts?

In this section, you will learn to:

- Configure a screened subnet.

The key terms for this section include:

Term	Definition
Screened subnet	A buffer network (or subnet) that is located between a private network and an untrusted network, such as the internet.
Bastion or sacrificial host	Any host that is exposed to attack and has been hardened or fortified against attack.
Screening router	The router that is most external to the network and closest to the internet.
Duel-homed gateway	A firewall device that typically has three network interfaces. One interface connects to the internet, one interface connects to the public subnet, and one interface connects to the private network.
Screened host gateway	A device residing within the screened subnet that requires users to authenticate in order to access resources within the screened subnet or the intranet.

This section helps you prepare for the following certification exam objectives:

Exam	Objective
CompTIA Security+ SY0-701	4.5 Given a scenario, modify enterprise capabilities to enhance security. • Firewall ○ Screened subnets
TestOut Security Pro	2.1 Harden Physical Access 2.1.4 Create and configure a screened subnet

5.3.1 Screened Subnets (Lesson Video)

Transcript:

In this lesson, we'll discuss screened subnets. A screened subnet allows you to expose an organization's services to the internet or other untrusted network while protecting the internal network. Implementing a screened subnet is part of a layered security approach.

Let's look at how a screened subnet works. Let's say you manage networks for a small company that provides driver downloads for their products. These drivers are accessed via a customer portal on your website, which is hosted on an in-house web server. The server resides in the company's internal network.
For customers to access this web server and download drivers, this server needs to be exposed to the internet. One way to do this is to place the web server outside the protected network. In other words, on the other side of the perimeter

firewall, right here. This would allow users to access the drivers that reside on this web server. However, this implementation would create a significant security issue.
This is because once you place the server outside the firewall, you have no control over what happens to it. Every hacker on the internet would be able to access this web server very easily and run all types of exploits on it. As you can see, this isn't a very good idea.
However, moving the web server inside the firewall presents another issue. Chances are this firewall allows outbound traffic but blocks all inbound traffic. This makes the web server invisible to the internet, and customers can't access the drivers. To solve this, you could add a rule in the firewall's ACL to allow connections using port 80, HTTP, and port 443, HTTP.
With these ports open, users can initiate connections from the internet to the web server. But, again, this has some risks. You've now opened two significant holes in the firewall here, which has the potential for security breaches. Many exploits take advantage of this scenario.
An attacker gains access to the web server box through the firewall using these two open ports. The attacker then perpetrates a variety of exploits on the web server, and since this web server is on the same network as the rest of the network, the attacker could compromise the entire network. So, what can be done?
One solution is to divide the network into multiple zones of different levels of security. You can create a high-security area and another area within the network that has a lower degree of security. You do this by creating a screened subnet. Let's look at how to do this.
First, you'll need to open ports 80 and 443 on the firewall to let internet users initiate connections to and access the web server. We still have our firewall in place. Opening these ports creates an area of low security on the network. The web server with open 80 and 443 ports is in the low-security area directly behind the firewall. To maintain the security of the rest of your network, you need to install a second firewall between this area of low security and your internal network. By doing this, you create a zone of high security for your internal network.
Because this web server resides in the low-security area with two ports open in the firewall, the web server resides in the screened subnet. The general rule is that you don't put anything in the screened subnet that doesn't absolutely need to be there. For example, the screened subnet isn't the place to put your payroll or your R&D servers. Only the servers and information accessed by users on the internet should be in the screened subnet.
There's still a risk in having this information on the web server. Someone could break in and, for example, replace one of the driver downloads with a modified version with a virus. Be aware of that risk and monitor the screened subnet for it.
The second high-security internal firewall behind the firewall keeps the low-security area of the network to this single segment. The internal network is secure behind the second firewall. When planning your firewall rules, a general rule is that you allow traffic originating in the secured internal network into the screened subnet and through to the internet.
For example, a user on your internal network should be able to open a web browser and access the internet through the various firewalls. However, you must not allow traffic that originates in the low-security area or the no-security area, which is the internet, to establish a connection with a host in the high-security area.
You can also create a screened subnet using a single firewall instead of two. In this scenario, one firewall now has two network connections and two network interfaces installed.
One interface connects to the internal high-security network. The second connects to a separate isolated network segment. You configure this firewall with different sets of rules for the different network segments.
You establish high-security firewall rules for the internal network, creating the area of high security. You implement lower-security rules, such as allowing traffic through ports 80 and 443 for this network segment where the web server resides. This creates a screened subnet security zone.
The lower-security rules for this network segment allow internet connections to the web server on ports 80 and 443. You should harden this server as much as possible because it's sitting in a lower-security area inside the screened subnet.
Each of these options has its strengths and weaknesses. The two-firewall system requires more hardware and, therefore, requires you to administer two separate firewall systems. The benefit is that an attack on the firewall has no effect on the internal firewall. Everything on the high-security network in the high-security zone could be functioning just fine while the firewall is experiencing continual attacks.
The single-firewall solution with multiple interfaces requires less hardware than the first solution. Therefore, you maintain only a single system. The single-firewall solution allows you to create multiple screened subnets. You can create multiple security zones with the one firewall device by adding additional interfaces. You could have a very high-security zone, a medium-security zone, and a low-security zone. The drawback to this approach is that it introduces a single point of failure. If that firewall goes down, everything else goes down with it.
In this lesson, we discussed screened subnets. We first defined what a screened subnet is. We then looked at different ways to create a screened subnet with multiple firewalls or a single firewall with multiple interfaces installed.

5.3.2 Configuring a Screened Subnet (Demo Video)

Transcript:

In this demonstration, we're going to create a screened subnet on our pfSense security appliance. Be aware that screened subnets are also referred to as demilitarized zones, or DMZs. Often, you will see them referred to as DMZs in software settings with various vendors. So, if we encounter something listed as DMZ, we are referring to a screened subnet.

For our current configuration, our device has two connections: LAN and WAN. As mentioned earlier, we are here to configure a screened subnet. I have a few extra optional ports on my pfSense device, and I'm going to configure one of these for the screened subnet. I'll also assign it the IP address 172.16.1.1. Let's get started.
The first thing I'll do from our pfSense Dashboard is confirm our current situation. You can see here that I have WAN and LAN interfaces. To add my screened subnet, I'll go to Interfaces > Assignments. On the Interface Assignments page, I'll click the Add button.
Here, I can see that OPT1 is displayed. I'll go ahead and click on it. OPT1 isn't a very descriptive name, so let's call it 'DMZ.' Before I forget, I'll check the box here to enable the interface. For IPv4 Configuration Type, I'll choose Static IPv4 from the list. We won't configure IPv6 for this demo. Now, let's scroll down to our Static IPv4 Configuration. As per my diagram, I said I was going to assign it the IP address '172.16.1.1,' so that's what I'll type in. I want to give it a /24 subnet mask.
That's all we need to do here. Click Save.
Now we can see the changes in our interface. It also says, "Don't forget to adjust the DHCP Server range if needed after applying." Let's go ahead and click on Apply Changes.
Let's configure our DHCP Server for our screened subnet. I'll go to Services > DHCP Server. We land on the page for the LAN DHCP Server. Let's go to the DHCP Server for the screened subnet.
I'll go ahead and enable DHCP for our screened subnet interface. Now we need to configure the range of IP addresses that our DHCP will hand out. I always leave IPs at the beginning of the range open for static addresses. I can pick something ending in .2 all the way up to .254. I'll set it to '172.16.1.100' and end at '172.16.1.199'. This way, I'll know that anything in the 100s was assigned via DHCP.
I'll scroll down and click Save.
Now let's go back to our dashboard and verify that our screened subnet interface is showing up. I'll scroll down, and right here, you can see that we have our screened subnet. This is where we can add devices to our screened subnet and configure our firewall for handling traffic going to and from the screened subnet.
That's it for this demo. In this demo, we configured a screened subnet.

5.3.3 Configure a Screened Subnet (Simulation)

Scenario

You are the IT administrator for a small corporate network. You want to make a web server that runs services accessible from the internet. To help protect your company, you want to place this server and other devices in a demilitarized zone (DMZ). This DMZ and server need to be protected by the pfSense Security Gateway Appliance (pfSense). Since a few of the other devices in the DMZ require an IP address, you have also decided to enable DHCP on the DMZ network.

In this lab, your task is to perform the following:

- Access the pfSense management console:
  - Username: **admin**
  - Password: **P@ssw0rd** (zero)
- Add a new pfSense interface that can be used for the DMZ.
  - Name the interface **DMZ** .
  - Use a static IPv4 address of **172.16.1.1/16** .
- Add a firewall rule for the DMZ interface that allows all traffic from the DMZ.

    - Use a description of **Allow DMZ to any rule** .
- Configure and enable the DHCP server for the DMZ interface.
    - Use a range of **172.16.1.100** to **172.16.1.200** .

Explanation

Complete this lab as follows:

1. Sign in to the pfSense management console.
    a. In the Username field, enter **admin** .
    b. In the Password field, enter **P@ssw0rd** (zero).
    c. Select **SIGN IN** or press **Enter** .
2. Configure an interface for the DMZ.
    a. From the pfSense menu bar, select **Interfaces** > **Assignments** .
    b. Select **Add** .
    c. Select **OPT1** .
    d. Select **Enable interface** .
    e. Change the Description field to **DMZ** .
    f. Under General Configuration, use the IPv4 Configuration Type drop-down menu to select **Static IPv4** .
    g. Under Static IPv4 Configuration, in the *IPv4 Address* field, enter **172.16.1.1** .
    h. Use the subnet mask drop-down menu to select **16** .
    i. Select **Save** .
    j. Select **Apply Changes** .
    k. (Optional) Verify the change as follows:
        - From the menu bar, select **pfsense COMMUNITY EDITION** .
        - Under Interfaces, verify that the DMZ is shown with the correct IP address.
3. Add a firewall rule to the DMZ interface.
    a. From the pfSense menu bar, select **Firewall** > **Rules** .
    b. Under the Firewall breadcrumb, select **DMZ** . (Notice that no rules have been created.)
    c. Under the Firewall breadcrumb, select **LAN** .
    d. Under the Actions column, select the **copy** icon (two files) for the rule with a source of **LAN net** .
    e. For the Action field, make sure **Pass** is selected.
    f. For the Interface field, use the drop-down menu to select **DMZ** .
    g. For Protocol, make sure it's set to **Any** .
    h. Under Source, use the drop-down menu to select **DMZ net** .
    i. Under Destination, make sure it is configured for **any** .
    j. Under Extra Options, change the description to **Allow DMZ to any rule** . (Is case sensitive.)
    k. Scroll to the bottom and select **Save** .
    l. Select **Apply Changes** .
4. Configure pfSense's DHCP server for the DMZ interface.
    a. From the menu bar, select **Services** > **DHCP Server** .
    b. Under the Services breadcrumb, select **DMZ** .
    c. Select **Enable** .
    d. Configure the Range field as follows:
        - From: **172.16.1.100**
        - To: **172.16.1.200**
    e. Scroll to the bottom and select **Save** .

5.3.4 Screened Subnet Facts

This lesson covers the following topics:

- Screened subnets
- Screened subnet terms

Screened Subnets

A screened subnet, also known as a perimeter network, creates an additional layer of protection between an organization's internal network and the internet. A screened subnet acts as a neutral zone, separating public-facing servers from sensitive internal network resources to reduce the exposure of the internal network resources to external threats. In practical terms, the screened subnet often hosts web, email, DNS, or FTP services. These systems must typically be accessible from the public internet but isolated from sensitive internal systems to limit the impact of a breach of one of these services. By placing these servers in the screened subnet, an organization can limit the damage if these servers are compromised.

Firewalls are typically used to create and control the traffic to and from the screened subnet. The first firewall, between the internet and the screened subnet, is configured to allow traffic to the services hosted in the screened subnet. The second firewall, between the screened subnet and the internal network, is configured to block most (practically all) traffic from the screened subnet to the internal network. A screened subnet is a fundamental part of a network's security architecture and an important example of network segmentation as a type of security control.

Be aware of the following screened subnet facts:

- If the firewall managing traffic into the screened subnet fails, only the servers in the screened subnet are subject to compromise. The LAN is protected by default.
- Packet filters on the firewall allow traffic directed to the public resources inside the screened subnet. Packet filters also prevent unauthorized traffic from reaching the private network.
- When designing the firewall packet filters, a common practice is to close all ports. Open only those ports necessary for accessing the public resources inside the screened subnet.
- To allow access to private resources from the internet, use one of the following approaches:
    - Place a VPN server inside the screened subnet. Require internet users to authenticate to the VPN server and then allow communications from the VPN server to the private network. Only communications coming through the VPN server are allowed through the inner firewall.
    - Copy resources accessible to internet users to servers inside the screened subnet. Even with authentication and authorization configured, this approach exposes those resources in the screened subnet to internet attacks.
- Typically, firewalls allow traffic originating in the secured internal network into the screened subnet and through to the internet. Traffic that originates in the screened subnet (low-security area) or the internet (no-security area) should not be allowed access to the intranet (high-security area).

Only place servers in the screened subnet that need to be there.

Screened Subnet Terms

The following terms are related to screened subnet.

Term	Definition
Bastion or sacrificial host	A bastion host is any host that is exposed to attack and that has been hardened (or fortified) against those attacks. The bastion host is sometimes referred to as a sacrificial host because it is assumed that it will be subject to attack. The term has been applied to the following types of devices:

	• A host that is exposed on the network and is not protected by a firewall device. • The device that provides the firewall service to the screened network behind it. Attacks must pass through the bastion host before they are allowed inside the screened subnet. • A honeypot device that is purposefully exposed to attack in order to distract attackers. The following actions should be taken to harden a bastion host: • Separate roles of bastion hosts by placing a single application on each server. • Fully patch your bastion host on the operating system and on applications. • Run current versions of antivirus and anti-spyware software. • Include a personal firewall. • Uninstall any unnecessary applications or utilities. • Disable and lock down all unnecessary services and ports. • Tighten security on the registry and the user database. • Add IP filters. • Run lockdown facilities, such as IIS lock down and URLScan.
Screening router	A screening router is the router that is most external to your network and closest to the internet. It uses access control lists (ACLs) to filter packets as a form of security. A firewall performing router functions is considered a screening router.
Dual-homed gateway	A dual-homed gateway is a firewall device that typically has three network interfaces: one connected to the internet, one connected to the public subnet, and one connected to the private network. Gateways have to be logged on to, whereas routers pass traffic through without user authentication. IP forwarding is disabled on gateways, effectively blocking through traffic to the network.
Screened-host gateway	A screened-host gateway resides within the screened subnet, requiring users to authenticate in order to access resources within the screened subnet or the intranet.
Two-firewall screened subnet	A screened subnet uses two firewalls. The external firewall is connected to the internet and allows access to public resources. The internal firewall connects the screened subnet to the private network. With a screened subnet, if the outer firewall is compromised, the inner firewall still protects the private network.

5.3.5 Practice Questions (Section Quiz)

q_dmz_bastion_secp8

Which of the following terms describes a network device that is exposed to attacks and has been hardened against those attacks?

Answers:

- ***Bastion or sacrificial host**
- Circuit proxy

- Kernel proxy
- Multi-homed

Explanation:

A bastion or sacrificial host is one that is unprotected by a firewall. The term bastion host is used to describe any device fortified against attack (such as a firewall). A sacrificial host might be a device intentionally exposed to attack, such as a honeypot.

Circuit proxy and kernel proxy are types of firewall devices.

Multi-homed describes a device with multiple network interface cards.

q_dmz_firewall_secp8

You have a company network that is connected to the internet. You want all users to have internet access, but you need to protect your private network and users. You also need to make a web server publicly available to internet users.

Which solution should you use?

Answers:

- ***Use firewalls to create a screened subnet. Place the web server inside the screened subnet and the private network behind the screened subnet.**
- Use firewalls to create a screened subnet. Place the web server and the private network inside the screened subnet.
- Use a single firewall. Put the web server in front of the firewall and the private network behind the firewall.
- Use a single firewall. Put the web server and the private network behind the firewall.

Explanation:

A screened subnet (or DMZ) is a buffer network (or subnet) that sits between the private network and an untrusted network such as the internet. A common configuration uses two firewalls, one connected to the public network and one connected to the private network. Publicly-accessible resources (servers) are placed inside the screened subnet. Examples of publicly-accessible resources include web, FTP, or email servers. Private resources that are not accessible from the internet are placed behind the screened subnet (behind the inner firewall).

Placing the web server inside the private network would mean opening ports in the firewall leading to the private network, which could expose other devices to attack. Placing the web server outside of the firewall would leave it unprotected.

q_dmz_homed_secp8

How many network interfaces does a dual-homed gateway typically have?

Answers:

- 1
- 2
- ***3**
- 4

Explanation:

A dual-homed gateway is a firewall device that typically has three network interfaces: one connected to the internet, one connected to the public subnet, and one connected to the private network.

q_dmz_packets_secp8

What needs to be configured on a firewall to allow traffic directed to the public resource in the screened subnet?

Answers:

- ***Packet filters**
- Subnet
- VPN
- FTP

Explanation:

Packet filters on the firewall allow traffic directed to the public resources inside the screened subnet. Packet filters also prevent unauthorized traffic from reaching the private network.

A subnet is used to segment a network.

A VPN provides a secure outside connection to an internal network's resources. A VPN does not need to be configured on the firewall to allow traffic to the public resource in the screened subnet.

FTP is a protocol used to transfer files. This does not need to be configured on the firewall to allow traffic to the public resource in the screened subnet.

q_dmz_private_secp8

You have used firewalls to create a demilitarized zone. You have a web server that needs to be accessible to internet users. The web server must communicate with a database server for retrieving product, customer, and order information.

How should you place devices on the network to BEST protect the servers? (Select two.)

Answers:

- ***Put the web server inside the screened subnet.**
- ***Put the database server on the private network.**
- Put the database server inside the screened subnet.
- Put the web server on the private network.
- Put the weber server and database server both behind the screened subnet.

Explanation:

Publicly accessible resources (servers) are placed inside the screened subnet. Examples of publicly accessible resources include web, FTP, or email servers. Devices that should not be accessible to public users are placed on the private network.

If you have a public server that communicates with another server, such as a database server, and that server should not have direct contact with public hosts, place the server on the private network and allow only traffic from the public server to cross the inner firewall.

q_dmz_public_secp8

In which of the following situations would you MOST likely implement a screened subnet?

Answers:

- You want internet users to see a single IP address when accessing your company network.
- ***You want to protect a public web server from attack.**
- You want to detect and respond to attacks in real time.
- You want to encrypt data sent between two hosts using the internet.

Explanation:

Use a screened subnet to protect public hosts on the internet, such as a web server, from attack. The screened subnet uses an outer firewall that prevents internet attacks. All publicly-accessible hosts are inside the screened subnet. A second firewall protects the private network from the internet.

Use a Virtual Private Network (VPN) to encrypt data between two hosts on the internet. Use Network Address Translation (NAT) to hide internal IP addresses from the internet. Use an Intrusion Prevention System (IPS) to detect and respond to threats in real time.

q_dmz_screened_subnet_01_secp8

Of the following security zones, which one can serve as a buffer network between a private secured network and the untrusted internet?

Answers:

- Intranet
- Extranet
- Padded cell
- ***Screened subnet**

Explanation:

A screened subnet (or DMZ) is a network placed between a private secured network and the untrusted internet to grant external users access to internally controlled services. The screened subnet serves as a buffer network.

An intranet is a private network that happens to employ internet information services.

An extranet is a division of a private network that is accessible to a limited number of users, such as business partners, suppliers, and certain customers.

A padded cell is an intrusion detection countermeasure used to delay intruders sufficiently to record meaningful information about them for discovery and prosecution.

q_dmz_screened_subnet_02_secp8

Which of the following is the MOST likely to happen if the firewall managing traffic into the screened subnet fails?

Answers:

- All devices in the screened subnet and LAN will be compromised.
- Nothing will happen - all devices will stay protected.

- ***Only the servers in the screened subnet are compromised, but the LAN will stay protected.**
- The LAN is compromised, but the screened subnet stays protected.

Explanation:

If the firewall managing traffic into the screened subnet fails, only the servers in the screened subnet are subject to compromise. The LAN is protected by default.

None of the other options are correct in this scenario.

q_dmz_screen_secp8

Which of the following is another name for a firewall that performs router functions?

Answers:

- Dual-homed gateway
- ***Screening router**
- Screened-host gateway
- Screened subnet

Explanation:

A firewall performing router functions is considered a screening router. A screening router is the router that is most external to your network and closest to the internet. It uses access control lists (ACLs) to filter packets as a form of security.

A dual-homed gateway is a firewall device that typically has three network interfaces: one connected to the internet, one connected to the public subnet, and one connected to the private network.

A screened-host gateway resides within the screened subnet, requiring users to authenticate in order to access resources within the screened subnet or the intranet.

A screened subnet uses two firewalls. The external firewall is connected to the internet and allows access to public resources. The internal firewall connects the screened subnet to the private network.

q_dmz_vpn_secp8

Which of the following is the BEST solution to allow access to private resources from the internet?

Answers:

- Packet filters
- Subnet
- ***VPN**
- FTP

Explanation:

A VPN provides a secure outside connection to an internal network's resources. A VPN server can be placed inside the screened subnet. Internet users can be required to authenticate to the VPN server and then allowed communications from the VPN server to the private network. Only communications coming through the VPN server are allowed through the inner firewall.

Packet filters on the firewall allow traffic directed to a public resource inside the screened subnet. Packet filters also prevent unauthorized traffic from reaching the private network. Packet filters won't allow access to private resources from the internet.

A subnet is used to segment a network.

File Transfer Protocol (FTP) is a protocol used to transfer files. This does not allow access to private resources from the internet.

5.4 Firewalls

As you study this section, answer the following questions:

- What is the difference between a network-based firewall and an application/host-based firewall?
- When would you choose to implement a host-based firewall?
- How are firewall rules used and what are they based on?
- What network security devices can be used for intrusion detection?
- Where should a network-based firewall be placed?

In this section, you will learn to:

- Configure firewall rules.
- Configure firewall schedules.
- Configure a perimeter firewall.

The key terms for this section include:

Term	Definition
Firewall	A device, or software running on a device, that inspects network traffic and allows or blocks traffic based on a set of rules.
Web application firewall (WAF)	A firewall designed specifically to protect software running on web servers and their back-end databases from code injection and DoS attacks.
Network firewall	A firewall that is used to regulate traffic in and out of an entire network.
Stateless firewall	A firewall that allows or denies traffic by examining information in IP packet headers.
Stateful firewall	A firewall that allows or denies traffic based on virtual circuits of sessions. A stateful firewall is also known as a circuit-level proxy or circuit-level gateway.

This section helps you prepare for the following certification exam objectives:

Exam	Objective

CompTIA Security+ SY0-701	2.5 Explain the purpose of mitigation techniques used to secure the enterprise
	• Hardening techniques
	  ○ Host-based firewall
	3.2 Given a scenario, apply security principles to secure enterprise infrastructure.
	• Firewall types
	  ○ Web application firewall (WAF)
	  ○ Unified threat management (UTM)

5.4.1 Firewalls (Lesson Video)

Transcript:

In the realm of network security, various tools and technologies stand as sentinels, guarding against the relentless tide of cyber threats. Among these defenders are

Web Application Firewalls, or WAFs, which serve as a defensive wall shielding web servers and their databases from the menacing attempts of code injection and denial-of-service attacks.
Imagine a fortress protecting the heart of a kingdom, the web server, and its valuable database. This fortress, equipped with a WAF, employs a sophisticated set of rules that are application-aware.' This means it not only understands the language of web traffic but also has the ability to detect and respond to threats specific to web applications. It's like having vigilant guards who can identify suspicious behavior in the crowd.
The WAF isn't just a passive guardian; it can be programmed with knowledge of known attack signatures. It acts like an ancient tome, filled with the wisdom of battles past, enabling it to recognize patterns that indicate malicious intent. When it detects these ominous signs, it raises its shield to block the attack. All of this is meticulously documented in logs, a record of the battles fought and threats thwarted, invaluable for understanding and fortifying the defenses.
A WAF can be likened to a powerful talisman, one that can be deployed as an independent appliance, creating a protective zone around the web server.
Alternatively, it can be seamlessly integrated as plug-in software, weaving its protective spells directly into the web server's fabric.
Moving forward, we encounter the Next-Generation Firewall, or NGFW, a transformative figure in the world of network security. The NGFW combines traditional firewall functionalities with advanced capabilities. It performs deep packet inspections, intrusion prevention, and application awareness.

At its core, the NGFW operates with a heightened sensitivity at Layer 7, the application layer. It's like having a security detail that not only checks the ID but also looks into the intentions of each guest. This includes inspecting encrypted traffic.
Moreover, NGFWs extend their protection by seamlessly integrating with network directories, enabling them to assign privileges and restrictions on a per-user or per-role basis. This way, they're equipped to deal with the insider threat, those who bear the disguise of trustworthiness.
Unified Threat Management, or UTM, is another noteworthy character in the realm of network security. It's like a commander who rallies troops from different battalions, bringing them together under one banner.
A UTM centralizes various security controls, like firewalls, anti-malware, and intrusion prevention, into a single, unified appliance. However, this consolidation, while efficient, carries a potential weakness. If the UTM falters, the entire defense line may crumble. It's akin to having all your eggs in one basket.
Additionally, UTM systems may struggle with latency issues bogged down by the weight of too much network activity. They might not perform as well as specialized devices in certain situations.
To some extent, the choice between NGFW and UTM is a matter of scale and need. UTM shines in small and medium-sized businesses where comprehensive security is required, but resources and expertise are limited. NGFW, on the other hand, is the choice for large businesses, offering better performance but with fewer all-encompassing features.
In the world of firewalls, there are two distinguished layers: Layer 4 and Layer 7. Layer 4, akin to a vigilant gatekeeper, inspects the transport layer, the OSI Layer 4. It carefully observes the TCP three-way handshake, ensuring connections are established following the proper protocol. Any deviations, such as suspicious SYN requests or irregular sequence numbers, are swiftly dealt with, preventing malicious attempts to flood or hijack sessions. It can even extend its gaze to UDP traffic, though this is a trickier endeavor due to the inherently connectionless nature of UDP.
Meanwhile, Layer 7, like an astute detective, dives even deeper. It delves into the application layer, the OSI Layer 7, analyzing not only the protocol but also the payload of application-layer packets. This heightened awareness allows it to verify whether the application protocol matches the assigned port.
Imagine a seasoned inspector who checks not only your credentials but also scrutinizes what you're wearing and your behavior.
For example, a Layer 7 firewall can spot a web application trying to send raw TCP data over an HTTP port, revealing hidden threats.
Access control lists, or ACLs, and firewall rules are akin to the rules and regulations governing entry and behavior within a secure facility. Think of ACLs as the bouncers at a club, deciding who gets in and who doesn't. They're like a list of permissions associated with devices like routers and switches.
They work at a network interface level, like a gatekeeper for each entrance.
ACLs use information from incoming packets, like where they're coming from (source IP), where they're going (destination IP), which door they're knocking on (port number), and even what they're saying (protocol).
These lists are used to control traffic across the network.
Now, imagine firewall rules as the instructions given to the bouncers. They tell them how to handle the guests.
Firewalls are like the security system for the whole club (your network). They protect it from unwanted guests and keep the party safe. These rules can be based on various factors, like where the guest is coming from (IP address), which doors they can use (port numbers), what language they're speaking (protocols), or even what kind of dance moves they're showing (application traffic patterns).
Here's the order in which the bouncers (ACLs) check the rules: 1) They start at the top of the list with the most specific rules and work their way down; 2) If a guest matches one of the rules (like having the right VIP pass), they're allowed inside; 3) If none of the rules match, there's usually a final rule that says, "Nobody else is allowed in" (implicit deny); and 4) Some firewalls might not have this final rule by default, so you can add a rule that explicitly denies all access.
It's not just about keeping threats out; firewall rules can also restrict outgoing traffic. Imagine a sieve that filters out undesirable elements from leaving the secure space. For example, a rule can be set to block all outgoing traffic on port 25 (SMTP), preventing a compromised machine from sending out spam emails.
That's it for this lesson. The world of network security is complex and ever-evolving, filled with guardians, gatekeepers, and detectives. Web Application Firewalls, Next-Generation Firewalls, Layer 4 and Layer 7 Firewalls, Access control lists, and firewall rules all play essential roles in fortifying the digital realm. In this digital age, where threats loom at every corner, the knowledge and implementation of proper security measures are paramount to safeguarding data and information.

5.4.2 Firewall Facts

This lesson covers the following topics:

- Firewall types
- ACLs and firewall rules

Firewall Types

A firewall is a network security device or software application that is designed to monitor, filter, and control incoming and outgoing network traffic based on predetermined security rules. The primary purpose of a firewall is to establish a barrier between a trusted internal network (such as a company's local area network or LAN) and untrusted external networks (such as the internet), thereby protecting the internal network from unauthorized access, cyberattacks, and other security threats.

The evolution of network security has given rise to specialized firewalls that offer different levels of protection and control. Depending on the specific security requirements and network architecture, organizations may use a combination of the following firewall types to secure their systems and data.

Type	Description
Host-based firewall	A host-based firewall inspects traffic received by a host. Use a host-based firewall to protect against attacks when there is no network-based firewall, such as when you connect to the internet from a public location. Host-based firewalls are typically software programs. A host-based firewall can be configured to meet the security requirements of the specific host and add an additional layer of security even when a network firewall has been implemented.
Network-based firewall	A network-based firewall inspects traffic as it flows between networks. For example, you can install a network-based firewall on the edge of your private network that connects to the internet to protect against attacks from internet hosts. Network-based firewalls are typically dedicated hardware devices.
Web application firewall	A web application firewall (WAF) is designed to protect software running on web servers and their back-end databases from code injection and denial-of-service attacks. WAFs use application-aware processing rules to filter traffic and perform application-specific intrusion detection. The WAF can be programmed with signatures of known attacks and use pattern matching to block requests containing suspect code. The output from a WAF will be written to a log, which can reveal potential threats to the web application.

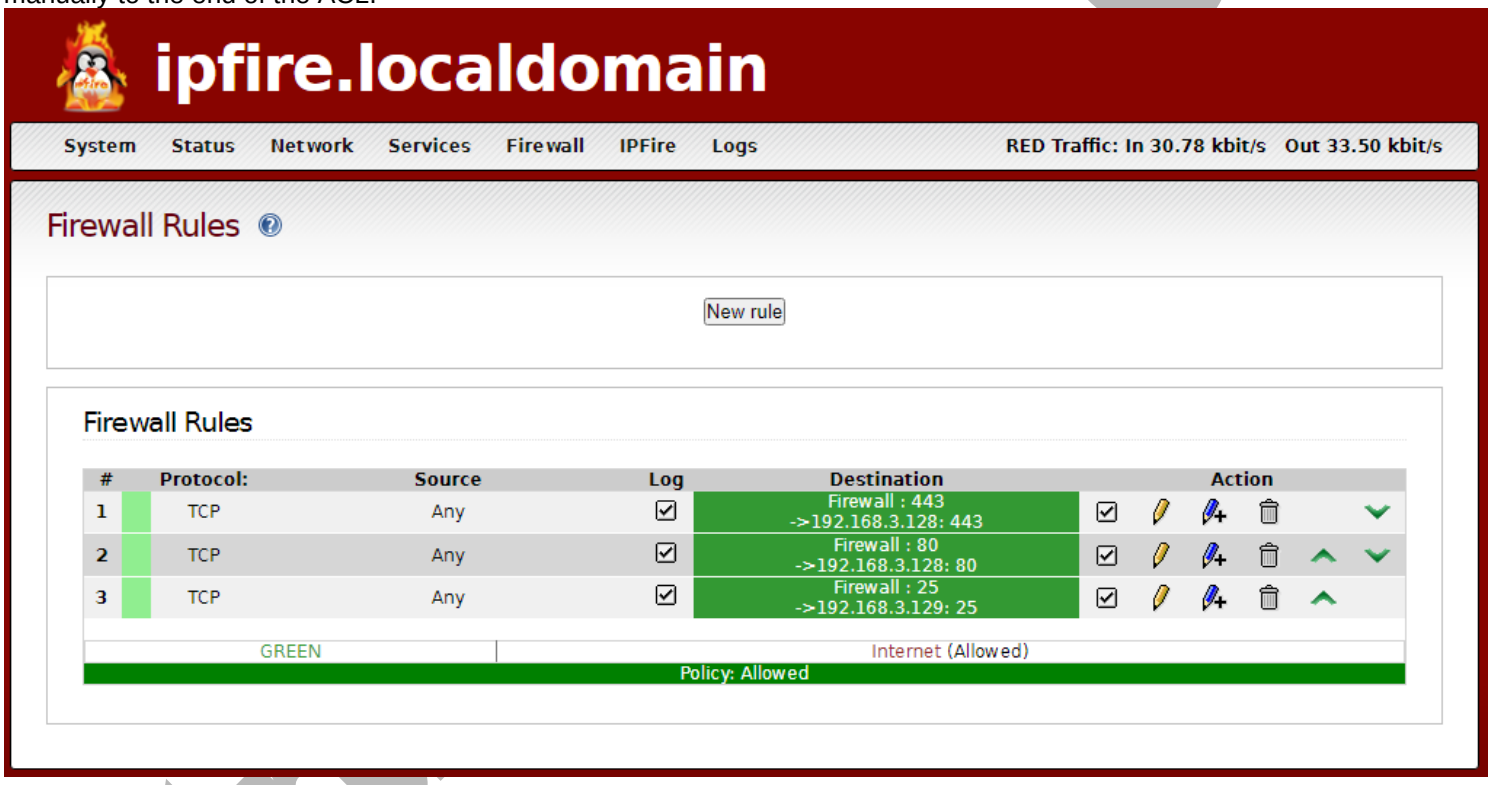
Type	Description
	 With the ModSecurity WAF installed to this IIS server, a scanning attempt has been detected and logged as an Application event. As you can see, the default ruleset generates a lot of events. (Screenshot used with permission from Microsoft.) A WAF may be deployed as an appliance protecting the zone that the web server is placed in or as plug-in software for a web server platform.
Next-generation firewall	While intrusion detection was originally produced as stand-alone software or appliances, its functionality quickly became incorporated into a new generation of firewalls. The original next-generation firewall (NGFW) was released in 2010 by Palo Alto. There is no official specification for what an NGFW can do, but the following features are typical: • Layer 7 application-aware filtering, including inspection of Transport Layer Security (TLS) encrypted traffic. • Integration with network directories, facilitating per-user or per-role content and time-based filtering policies, providing better protection against an insider threat. • Intrusion prevention system (IPS) functionality. Next-generation firewalls can combine traditional firewall functionalities with advanced capabilities, such as deep packet inspection, intrusion prevention, and application awareness. • Integration with cloud networking.

Type	Description
Unified threat management	Unified threat management (UTM) refers to a security product that centralizes many types of security controls—firewall, antimalware, network intrusion prevention, spam filtering, content filtering, data loss prevention, virtual private networking (VPN), cloud access gateway, and endpoint protection/malware scanning—into a single appliance. This means monitoring and management of diverse controls are consolidated into a single console. UTM has some downsides. • When a defense is unified under a single system, this creates the potential for a single point of failure that could affect an entire network. Distinct security systems, if they fail, might only compromise that particular avenue of attack. • Additionally, UTM systems can struggle with latency issues if subject to too much network activity. Also, a UTM might not perform as well as software or a device with a single dedicated security function. To some extent, NGFW and UTM are just marketing terms. UTM is commonly deployed in small and medium-sized businesses that require a comprehensive security solution but have limited resources and IT expertise. A UTM is seen as a turnkey "do everything" solution, while a NGFW is an enterprise product with fewer features but better performance.
Stateless firewall	A basic packet filtering firewall is stateless. This means that it does not preserve information about network sessions. Each packet is analyzed independently, with no record of previously processed packets. This type of filtering requires the least processing effort, but it can be vulnerable to attacks spread over a sequence of packets. A stateless firewall can also introduce problems in traffic flow, especially when using some sort of load balancing or when clients or servers need to use dynamically assigned ports.
Stateful firewall	A stateful inspection firewall tracks information about the session established between two hosts. All firewalls now incorporate some level of stateful inspection capability. Session data is stored in a state table. When a packet arrives, the firewall checks it to confirm whether it belongs to an existing connection. If it does not, it applies the ordinary packet filtering rules to determine whether to allow it. Once the connection has been allowed, the firewall usually allows traffic to pass unmonitored in order to conserve processing effort.
Layer 4 firewall	Layer 4 is the OSI transport layer. A layer 4 firewall examines the TCP three-way handshake to distinguish new from established connections. A legitimate TCP connection should follow a SYN > SYN/ACK > ACK sequence to establish a session, which is then tracked using sequence numbers. Deviations from this, such as SYN without ACK or sequence number anomalies, can be dropped as malicious flooding or session hijacking attempts. The firewall can be configured to respond to such attacks by blocking source IP addresses and throttling sessions. It can also track UDP traffic, though this is harder as UDP is a protocol without connections. It is also likely to be able to detect IP header and ICMP anomalies.
Layer 7 firewall	A layer 7 firewall can inspect the headers and payload of application-layer packets. One key feature is to verify the application protocol matches the port because malware can try to send raw TCP data over port 80 just because port 80 is open, for instance. As another example, a web application firewall could analyze the HTTP headers and the webpage formatting code present in HTTP packets to identify strings that match a pattern in its threat database. Application-aware firewalls have many different names, including application layer gateway, stateful multilayer inspection, and deep packet inspection. Application-aware devices have to be configured with separate filters for each type of traffic (HTTP and HTTPS, SMTP/POP/IMAP, FTP, and so on).

ACLs and Firewall Rules

An access control list (ACL) is a list of permissions associated with a network object, such as a router or switch, that controls traffic at a network interface level. ACLs typically use packet information like source and destination IP addresses, port numbers, and the protocol to decide whether to permit or deny the traffic. They are usually implemented on network devices to provide traffic control across the network, adding a layer of security and efficiency. In contrast, a firewall rule dictates how firewalls should handle inbound or outbound network traffic for specific IP addresses, IP ranges, or network interfaces. Firewalls typically provide both network and application-level control. They are designed to protect a network perimeter by preventing unauthorized access to or from a network. Firewall rules can be based on various factors, such as IP addresses, port numbers, protocols, or even specific application traffic patterns.

The rules in a firewall's ACL are processed from top to bottom. If traffic matches one of the rules, then it is allowed to pass; consequently, the most specific rules are placed at the top. The final default rule is typically to block any traffic that has not matched a rule (implicit deny). If the firewall does not have a default implicit deny rule, an explicit deny all rule can be added manually to the end of the ACL.



(Screenshot used with permission from IPFire)

Each rule can specify whether to block or allow traffic based on several parameters, often referred to as tuples. If you think of each rule being like a row in a database, the tuples are the columns. For example, in the previous screenshot, the tuples include Protocol, Source (address), (Source) Port, Destination (address), (Destination) Port, and so on.

Even the simplest packet-filtering firewall can be complex to configure securely. It is essential to create a written policy describing what a filter ruleset should do and to test the configuration as far as possible to ensure that the ACLs you have set up work as intended. Also, test and document changes made to ACLs. Some other basic principles include the following:

- Block incoming requests from internal or private IP addresses (that have obviously been spoofed).
- Block incoming requests from protocols that should only function at a local network level, such as ICMP, DHCP, or routing protocol traffic.

- Use penetration testing to confirm the configuration is secure. Log access attempts and monitor the logs for suspicious activity.
- Take the usual steps to secure the hardware on which the firewall is running and use the management interface.

For instance, a firewall rule can be specifically designed to permit or deny traffic based on the TCP or UDP port numbers that a service operates on. If a web server on a network should only allow incoming HTTP and HTTPS traffic, rules could be set up to allow traffic only on ports 80 (HTTP) and 443 (HTTPS), the standard ports for these services. Similarly, rules can be defined to restrict certain protocols such as FTP or SSH from entering the network if they are not needed, thereby reducing the potential attack surface.

Additionally, you can use firewall rules to restrict outgoing traffic to prevent certain types of communication from inside the network. For instance, a rule can block all outgoing traffic to port 25 (SMTP) to prevent a compromised machine within the network from sending out spam emails.

5.4.3 Configuring Firewall Rules (Demo Video)

Transcript:

In this demonstration, we're going to configure firewall rules on a pfSense security appliance. First, we're going to configure a firewall rule to allow both HTTP and HTTPS traffic from the internet, or WAN, through the firewall and to our web server on our screened subnet. The second thing we're going to do is configure a rule to allow all traffic coming from our LAN to get to our screened subnet through the firewall. Be aware that when we are talking about a screened subnet, some vendors may refer to this as a demilitarized zone, or DMZ.

I want to verify that I have my screened subnet ready to go. I'll scroll down, and you can see I have my three interfaces here, and they have assigned IPs.
Let's create our rules. I'll go to Firewall > Rules, and the first rules I'll configure are the ones from our WAN to our screened subnet to allow HTTP and HTTPS to our web server. I want to go to the DMZ tab here, and down here, I have a few buttons. You'll notice there are two buttons that say Add. This one has the arrow pointing up, and if I pick that one, it'll add the rule to the top of my list. If I click on the one with the arrow pointing down, it'll add the rule to the bottom, so I'll click on that one.
For our rule, we want to choose to pass the traffic through the firewall. My other choices are to block it or reject it. If we choose Block, it will just drop the packets as if they never arrived If we choose Reject, the packets are returned to the sender, and the sender can see they were blocked. For security reasons, sometimes you don't want senders to know that your device is even there, and it's better to just block the packets. But if you're troubleshooting issues, reject can be more helpful. Either way, with block or reject, the packets won't reach the destination.
The interface that I want to configure is the DMZ. You can see that I have my LAN and WAN here as well. For Address Family, I'll leave it as IPv4. The other choices are IPv6 or both. For Protocol, we're allowing HTTP, which runs on TCP. If I click the dropdown list, you can see all the other protocols that we could choose if we were going to allow some other type of traffic.
Our source is going to be from our WAN network. I need to see more options, so I'll click on the Display Advanced button. The Source Port Range is going to be HTTP. I could put in a single port or a range, but we just want HTTP port 80. Since this is going to be my web server, I need to put in the IP address here. First, I'll pick Single host or alias, and now let's pop our diagram back up. Our web server's IP is right here, so let's go back and enter that in. Destination Address will be '172.16.1.5'. We're using HTTP, and the rest of this looks good.
Down here, we could log packets handled by this rule. Since this is a web server, we probably don't want to do that since our log would be overwhelmed. If it was FTP, SSH, or other traffic like that, we probably would want to log traffic, but not for normal web requests. We do want to put a description in here because as you create more and more rules, you'll forget what they all do. For this, I'll type in 'HTTP to DMZ from WAN' and click Save. On our next page here, we have to click on Apply Changes for the changes to my firewall to take effect.
So, here are my rules so far. I have one that allows my screened subnet out, and this second one is our HTTP rule from the WAN on port 80 the web server on our screened subnet.
Now, you might be saying to yourself, "Doesn't most web traffic use HTTPS these days?" Well, that answer is certainly yes, so now we need an HTTPS rule.

Here's some good news: to save a bit of time and keep from making any errors, we can just copy this rule and change the HTTP port 80 to HTTPS port 443. I'll click here, which is the Copy icon. What this does creates a new rule with the exact settings. I'll scroll down and change my source from HTTP port 80 to HTTPS port 443. For the destination, I'll do the same. Scroll down change the description by just adding the letter 'S'. Click Save. On this page, Click Apply Changes. Down here, you now see our rules for both HTTP and HTTPS.
Now let's look at our diagram again. This time, I want to create a rule that allows any traffic from my LAN to get to the screened subnet. Let's go back to our firewall and configure that now. These rules are read from the top down. So, for example, if the first rule says block everything, none of the other rules would ever be seen because that's the very first rule. However, if we made a rule right now that said to block everything and put it at the bottom, our first three rules would still be fine, but everything else would be blocked. By default, everything is blocked with pfSense anyway unless you open it, so we wouldn't really need that sort of rule, but it doesn't hurt anything. So far, our rules don't affect one another, so it really doesn't matter where we put them, but keep all of this in mind when creating rules. We'll just click on Add and use the one that puts it at the bottom of the list.
Our Action will be to pass traffic. We'll leave the interface and address family alone. But for protocol, we're going to change this from TCP to Any. This might not be the best practice, but we're allowing any and all traffic from our LAN to reach our screened subnet. Under Source, we'll choose our LAN network from the list. Our destination will be the screened subnet from this list. We don't want to forget a description for this rule. I'll type 'LAN to DMZ Any'. Click Save. As always, Apply Changes.
Here's my latest rule. My source is from the LAN on any port to my DMZ on any port. By the way, the asterisk is wildcard, which means any. Over here, the green check mark means it's enabled.
That's it for this demo. In this demo, we created firewall rules on our firewall.

5.4.4 Configure Firewall Schedules (Demo Video)

Transcript:

There may be times when you want to restrict certain groups of users' access to the internet or other services. For example, you might allow SSH through the firewall to a Linux server, but the person who needs access to it only has it during work hours. Another example is a school that doesn't want normal users accessing the web after hours. There are many cases when you'd want to configure restrictions. For our demo, we're going to use a scenario of blocking web traffic, or HTTP traffic, after business hours.

This is basically a three-part process. First, we'll create a time-restriction schedule. Then we're going to create a rule and apply that schedule to our users. The last thing we'll do is create a rule to override the restriction for members of our management group.
So, under Firewall > Schedules, I go over to Add and click on it. I need to give it a Schedule Name. This can't have any spaces in it, so I'll use underscores and call it Allow_Web_Work _Hours. For our Description we can use anything. I'll call it Allow Web During Work Hours.
For the days, I'll click on the workdays of Monday through Friday to add all of them. For Time, I'll pick 7:00 a.m. from the dropdown list and jump over to Stop Hours. Here, I'll pick 17 and leave the minutes at 59. That makes our stop time 5:59 p.m. I'll click on Add Time, and you can see my Configured Range here, which is now Monday through Friday from 7:00 a.m. to 17:59. That looks good, so let's click Save. Now we're done with our schedule. Next, we need to configure our firewall rules.
We now need to go up to Firewall > Rules and then click on our LAN tab to get to our LAN firewall rules. We have a few rules. One basically allows IPv4 out to anywhere and the same for IPv6.
We want to add our rule to the top of the list. So I'll pick Add with the arrow pointing up.
We want to select Block because we're going to block traffic based on the schedule. I'll scroll down.
We're going to block everything on our LAN network, so I'll pick LAN net from the dropdown list. I need to click on the Display Advanced button here. Now, for our Source Port Range we want to block HTTP port 80.
Let's scroll down a bit. Under Extra Options, click on Display Advance to see additional options. We need to come down and find where it says Schedule. From the list, we have all our schedules. And since we only created one, that's all we have. Let's pick that one. Go down and click on Save.
Now we see our new rule. The source is the LAN network on port 80. Over here, you can see that it refers to the schedule that we created. This all looks good, and so we go up and click Apply Changes.

We have our schedule and we've created a rule that applies that schedule to our users. But what about users that we want to have access to the internet no matter what time of day it is? We need to create another rule for that. But first we need to create an alias. An alias is a group of IPs that'll be grouped together. That alias will be added to a rule that allows internet access.
To do that, we go up to Firewall > Aliases. When the page loads, we go down to the Add button. We need to give it a name that we'll use to identify this group of IP addresses. We'll just say that this group is our management. So, for the Name field that's what I'll put in. I'll do the same for Description.
Now I need to enter in the IP addresses of those devices that'll be part of this alias. I'll enter in a few and start with 10.10.10.1. That IP belongs to Dana. Click Add Host. Now let's enter 10.10.10.2; that'll be Jon's. Click Add Host and we'll add one more, which is 10.10.10.3. That'll be for Mary. Click Add Host one final time and then click Save. Apply the changes and we're ready to create our final rule.
Now that we have our alias, we need to create our rule to override the rule that blocks web access for all users. These rules will be from the top down. If our firewall reads the first rule that says to block all HTTP traffic during non-work hours, that rule is applied. The rule that says to allow management access will never be seen. So, we need to make sure that we tell our firewall that our management can have access before we tell it to block everyone else. We go to Firewall > Rules > LAN and then click the Add button with the up arrow.
All the settings here are fine. But down here, under Source, we need to change this to Single host or alias. Now, watch as I start to type in the address field. As soon as I start to type in Management, it auto-populates with our alias. We'll leave the destination set to Any. For Description, I'll type in Allow Management Web Access Anytime. Click on Save and the rule is created.
As a quick side note, this first rule is created automatically by pfSense. It's there to prevent you from creating any rule that might accidently block you from gaining access to the firewall. That's why it's first in this position. You can actually remove that rule, but that's not part of this lesson. Right below that is our rule. The rule we create for management will be applied before the block web access rule. The one right below it is applied.
That's it for this demo. In this demo, we created a schedule on our firewall to deny web access to our users. Then we created an alias for a group of users who are allowed to bypass that rule with a second rule.

5.4.5 Configure a Perimeter Firewall (Simulation)

Scenario

You work as the IT security administrator for a small corporate network. You recently placed a Web server in the demilitarized zone (DMZ). You need to configure the perimeter firewall on the network security appliance (pfSense) to allow access from the WAN to the Web server in the DMZ using both HTTP and HTTPs. You also want to allow all traffic from the LAN network to the DMZ network.

In this lab, your task is to:

- Access the pfSense management console:
  - Username: **admin**
  - Password: **P@ssw0rd** (zero)
- Create and configure a firewall rule to pass HTTP traffic from the WAN to the Web server in the DMZ.
- Create and configure a firewall rule to pass HTTPS traffic from the WAN to the Web server in the DMZ.
  - Use the following table when creating the HTTP and HTTPS firewall rules:

Parameter	Setting
Source	WAN network
Destination port/service	HTTP (80), HTTPS (443)

Destination	A single host
IP address for host	172.16.1.5
Descriptions	For HTTP: HTTP from WAN to DMZ For HTTPS: HTTPS from WAN to DMZ

- Create and configure a firewall rule to pass all traffic from the LAN network to the DMZ network. Use the description *LAN to DMZ Any* .

Explanation

Complete this lab as follows:

1. Sign in to the pfSense management console.
    a. In the Username field, enter **admin** .
    b. In the Password field, enter **P@ssw0rd** (zero).
    c. Select **SIGN IN** or press **Enter** .
2. Create and configure a firewall rule to pass HTTP traffic from the WAN to the Web server in the DMZ.
    a. From the pfSense menu bar, select **Firewall** > **Rules** .
    b. Under the Firewall breadcrumb, select **DMZ** .
    c. Select **Add** (either one).
    d. Make sure Action is set to **Pass** .
    e. Under Source, use the drop-down to select **WAN net** .
    f. Under Destination, use the Destination drop-down to select **Single host or alias** .
    g. In the Destination Address field, enter **172.16.1.5** .
    h. Using the Destination Port Range drop-down, select **HTTP (80)** .
    i. Under Extra Options, in the Description field, enter **HTTP from WAN to DMZ** .
    j. Select **Save** .
    k. Select **Apply Changes** .
3. Create and configure a firewall rule to pass HTTPS traffic from the WAN to the Web server in the DMZ.
    a. For the rule just created, select the ***Copy*** icon (two files).
    b. Under Destination, change the Destination Port Range to **HTTPS (443)** .
    c. Under Extra Options, change the Description field to **HTTPS from WAN to DMZ** .
    d. Select **Save** .
    e. Select **Apply Changes** .
4. Create and configure a firewall rule to pass all traffic from the LAN network to the DMZ network.
    a. Select **Add** (either one).
    b. Make sure Action is set to **Pass** .
    c. For Protocol, use the drop-down to select **Any** .
    d. Under Source, use the drop-down to select **LAN net** .
    e. Under Destination, use the drop-down to select **DMZ net** .
    f. Under Extra Options, change the Description field to **LAN to DMZ Any** .
    g. Select **Save** .
    h. Select **Apply Changes** .

5.4.6 Practice Questions (Section Quiz)

q_firewalls_acl_01_secp8

Which of the following does a router acting as a firewall use to control which packets are forwarded or dropped?

Answers:

- ***ACL**
- IPsec
- RDP
- VNC
- PPP

Explanation:

When you configure a router as a firewall, you configure the access control list (ACL) with statements that identify traffic characteristics, such as the direction of traffic (inbound or outbound), the source or destination IP address, and the port number. ACL statements include an action to either allow or deny the traffic specified by the ACL statement.

IPsec is a protocol for encrypting packets.

RDP and VNC are remote desktop protocols used for remotely accessing a computer's desktop.

PPP is a protocol for establishing a remote access connection over a dial-up link.

q_firewalls_acl_02_secp8

Which of the following describes how access control lists can be used to improve network security?

Answers:

- ***An access control list filters traffic based on the IP header information, such as source or destination IP address, protocol, or socket number.**
- An access control list looks for patterns of traffic between multiple packets and takes action to stop detected attacks.
- An access control list filters traffic based on the frame header, such as source or destination MAC address.
- An access control list identifies traffic that must use authentication or encryption.

Explanation:

An access control list filters traffic based on the IP header information, such as source or destination IP address, protocol, or socket number. Access control lists are configured on routers, and they operate on Layer 3 information.

Port security is configured on switches, which filter traffic based on the MAC address in the frame.

An intrusion detection system (IDS) or intrusion prevention system (IPS) examines patterns detected across multiple packets.

An IPS can take action when a suspicious pattern of traffic is detected.

q_firewalls_acl_03_secp8

A financial institution has recently undergone a significant network infrastructure upgrade and plans to enhance its network security. It is considering incorporating access control lists (ACLs) into its firewall rules and wants to establish a screened subnet for better security.

Which of the following options would be the MOST beneficial course of action?

Answers:

- ***Incorporate ACLs into its firewall rules and set up a screened subnet**
- Maintain the existing firewall rules and ignore ACLs and screened subnet
- Implement ACLs in its firewall and avoid creating a screened subnet
- Establish a screened subnet but keep the existing firewall rules

Explanation:

Incorporating ACLs into the institution's firewall rules will provide more precise control over traffic based on various parameters. Simultaneously, setting up a screened subnet can isolate public-facing servers from sensitive internal network resources, thus reducing the exposure of the internal network to external threats.

Keeping the current firewall rules without considering ACLs or a screened subnet may leave the institution vulnerable to more advanced threats.

While implementing ACLs in the firewall enhances traffic control and security, not setting up a screened subnet misses an opportunity to reduce the exposure of internal network resources to external threats.

Establishing a screened subnet is a good security practice; however, keeping the existing firewall rules without integrating ACLs misses out on granular traffic control.

q_firewalls_acl_04_secp8

A company's web server is openly accessible to the internet, demanding heightened security measures.

Considering the need for essential protocols and the introduction of a screened subnet, how should the company configure the firewall's access control lists (ACLs)?

Answers:

- ***Permit Hypertext Transfer Protocol (HTTP) and Hypertext Transfer Protocol Secure (HTTPS) on firewall access control lists (ACLs); establish a screened subnet for the web server.**
- Block all ports and protocols; enable a screened subnet for the server.
- Allow all ports and protocols; do not create a screened subnet.
- Permit only FTP, SSH, and enable File Integrity Monitoring; disregard screened subnet implementation.

Explanation:

Permitting Hypertext Transfer Protocol (HTTP) and Hypertext Transfer Protocol Secure (HTTPS) on the firewall ACLs establishes a screened subnet and adds a layer of security by isolating the server from the internal network, minimizing potential damage from a breach.

Blocking all ports and protocols would hinder the web server's operation. Although a screened subnet would add a layer of security, it doesn't replace the need for well-configured ACLs.

Allowing all ports and protocols introduces unnecessary security risks. Foregoing the creation of a screened subnet misses a crucial opportunity to further isolate and protect the server.

Permitting only FTP and SSH on the firewall ACLs without a screened subnet lacks comprehensive security.

q_firewalls_acl_deny_access_secp8

A security administrator reviews the network configurations of a recently deployed server. The administrator notices that certain unnecessary services have access to the server, potentially creating vulnerabilities. The administrator decides to refine the access control list (ACL) to enhance the server's security.

Which action will the security administrator MOST likely take when refining the ACL to ensure that only necessary services communicate with the server, thereby reducing potential attack vectors?

Answers:

- Permit all incoming traffic to maintain functionality by default
- ***Deny all traffic by default and then allow exceptions based on requirement**
- Permit traffic only from trusted MAC addresses by default
- Implement a stateful firewall for the server

Explanation:

When securing an ACL, best practices dictate denying all traffic by default and permitting only necessary specific traffic. This "deny by default" principle ensures that only approved traffic accesses the resource.

Permitting all incoming traffic creates vulnerabilities since it fails to distinguish between necessary and unnecessary services.

Permitting traffic only from trusted MAC addresses by default does not adhere to the ACL best practice of first denying all traffic by default.

A stateful inspection firewall tracks information about the session established between two hosts, and inspects a packet when it arrives to confirm whether it belongs to an existing connection. If it does not, it applies the ordinary packet filtering rules to determine whether to allow it. This approach does not adhere to the ACL best practice of first denying all traffic by default.

q_firewalls_application_secp8

Which of the following are features of an application-level gateway? (Select two.)

Answers:

- Allows only valid packets within approved sessions
- Uses access control lists
- Verifies that packets are properly sequenced
- ***Reassembles entire messages**
- ***Stops each packet at the firewall for inspection**

Explanation:

Application-level gateways:

- Operate up to OSL Layer 7 (Application layer)
- Stop each packet at the firewall for inspection (no IP forwarding)
- Inspect encrypted packets, such as an SSL inspection
- Examine the entire content that is sent (not just individual packets)
- Understand or interface with the application-layer protocol
- Can filter based on user, group, and data (such as URLs within an HTTP request)

- Is the slowest form of firewall protection because entire messages are reassembled at the Application layer

Allowing only valid packets within approved sessions and verifying that packets are properly sequenced are features of a stateful firewall.

Using access control lists is a feature of a packet-filtering firewall.

q_firewalls_deep_packet_secp8

An IT specialist working for a multinational confectionery company needs to fortify its network security. The firm has been dealing with intrusions where raw User Datagram Protocol (UDP) packets bypass open ports due to a virus.

The specialist will analyze packet data to verify that the application protocol corresponds to the port. The company also wants to track the state of sessions and prevent fraudulent session initiations.

Which of the following tools should the IT specialist prioritize deploying?

Answers:

- ***Deep packet inspection firewall**
- Circuit-level gateway
- Packet filtering firewall
- Transparent firewall

Explanation:

A deep packet inspection firewall acting on layer 7 can scrutinize the content of application packets and confirm protocol-port compatibility. It can also monitor the state of sessions and prevent fraudulent sessions.

A circuit-level gateway, also known as a circuit-level stateful inspection firewall, operates at the session layer and can monitor established connections. However, it falls short of verifying application protocols.

Packet filtering firewalls cannot retain details about network sessions, examining packets independently. They do not maintain session states or validate application protocols.

Although a transparent firewall can review traffic moving between two nodes and operates like a bridge, it cannot scrutinize packet contents at layer 7.

q_firewalls_defense_in_depth_secp8

Which of the following describes the placement and role of a firewall in a network with a defense-in-depth strategy?

Answers:

- A firewall is typically at the network border and serves as a detective control to identify malicious traffic.
- ***A firewall is typically at the network border and serves as a preventive control to enforce access rules for ingress and egress traffic.**
- A firewall is typically inline behind the border firewall and serves as a preventive control to enforce access rules.
- A firewall is typically on internal routers and serves as a corrective control to mitigate denial-of-service (DoS) attacks.

Explanation:

In a network with a defense-in-depth strategy, a firewall is usually at the network border and serves as a preventive control. Its main function is to enforce access rules for traffic entering (ingress) and leaving (egress) the network.

A firewall serves primarily as a preventive control to enforce access rules, not as a detective control to identify malicious traffic.

A firewall is typically at the network border, not inline behind another firewall, to enforce access rules.

While a firewall can mitigate certain types of attacks, it is not typically on internal routers and is not primarily a corrective control for DoS attacks.

q_firewalls_firewall_secp8

Which of the following is the BEST device to deploy to protect your private network from a public untrusted network?

Answers:

- ***Firewall**
- Router
- Hub
- Gateway

Explanation:

A firewall is the best device to deploy to protect your private network from a public untrusted network. Firewalls are used to control traffic entering and leaving your trusted network environment. Firewalls can manage traffic based on source or destination IP address, port number, service protocol, application or service type, user account, and even traffic content.

Routers offer some packet-based access control, but it is not as extensive as that of a full-fledged firewall.

Hubs and gateways are not sufficient for managing the interface between a trusted and an untrusted network.

q_firewalls_hardware_secp8

Jessica needs to set up a firewall to protect her internal network from the internet.

Which of the following would be the BEST type of firewall for her to use?

Answers:

- ***Hardware**
- Tunneling
- Stateful
- Software

Explanation:

Hardware firewalls are physical devices that are usually placed at the junction or gateway between two networks, generally a private network and a public network like the internet. Hardware firewalls can be a standalone product or can also be built into devices like broadband routers.

Software firewalls are generally used to protect individual hosts.

Tunneling is when an attacker wraps a malicious command in an HTTP, ICMP, or ACK tunneling packet that bypasses the firewall and reaches an internal system.

Stateful firewalls, also referred to as stateful multilayer firewalls, determine the legitimacy of traffic based on the state of the connection from which the traffic originated.

q_firewalls_host-based_secp8

A cyber team implements new hardening techniques after a data loss prevention (DLP) audit revealed increased data exfiltration.

What is a tenet of host-based firewalls?

Answers:

- ***It provides controls for incoming and outgoing network traffic.**
- It describes software tools that monitor and protect individual hosts.
- It requires deploying and configuring specialized software agents.
- It uses signature-based detection and anomaly detection.

Explanation:

Host-based firewalls provide controls for incoming and outgoing network traffic and are essential for detecting potential attacks. An important technique for using them when hardening endpoints involves implementing default-deny policies to block all traffic unless explicitly allowed.

Host-based intrusion prevention (HIPS) describes software tools that monitor and protect individual hosts, like computers or servers, from unauthorized access and malicious activities.

HIPS requires deploying and configuring specialized software agents to continuously monitor and analyze endpoints.

HIPS systems use signature-based detection, anomaly detection, and behavior analysis to identify suspicious activities. They also detect and actively respond to threats by automatically blocking or mitigating them.

q_firewalls_host_01_secp8

You have been given a laptop to use for work. You connect the laptop to your company network, use it from home, and use it while traveling.

You want to protect the laptop from internet-based attacks.

Which solution should you use?

Answers:

- ***Host-based firewall**
- Network-based firewall
- VPN concentrator
- Proxy server

Explanation:

A host-based firewall inspects traffic received by a host. Use a host-based firewall to protect against attacks when there is no network-based firewall, such as when you connect to the internet from a public location.

A network-based firewall inspects traffic as it flows between networks. For example, you can install a network-based firewall on the edge of your private network that connects to the internet to protect against attacks from internet hosts.

A VPN concentrator is a device connected to the edge of a private network that is used for remote access VPN connections. Remote clients establish a VPN connection to the VPN concentrator and are granted access to the private network.

A proxy server is an Application-level firewall that acts as an intermediary between a secure private network and the public. Access to the public network from the private network goes through the proxy server.

q_firewalls_host_02_secp8

A new IT tech reviews changes made to a computer, including turning off unneeded logical ports, installing a host-based firewall, and updating the installed antivirus software.

These actions are examples of what technique?

Answers:

- ***Securing the system against a network attack**
- Controlling access to the system
- Implementing host-based intrusion detection/prevention
- Following a baseline configuration and registry settings

Explanation:

Protecting a system from a network-based attack includes disabling unneeded logical ports, installing a host-based firewall, and updating the local antivirus software.

These steps do not assist in controlling access to the system. The steps outlined will help make a system more secure overall, especially when the steps to protect against a network attack pair with steps to harden the system from local attacks.

Host-based intrusion detection and intrusion prevention systems (HIDS/HIPS) require deploying and configuring specialized software agents that continuously monitor and analyze endpoints.

Companies install baseline configuration and registry settings (BCRS) by default and automatically apply the registry settings.

q_firewalls_layer_7_secp8

The network security engineer at a financial corporation is reviewing the current firewall setup. The corporation faces threats from various cyberattacks, some of which leverage application-specific vulnerabilities.

The engineer is considering whether to deploy Layer 4 or Layer 7 firewalls for enhanced security.

If the primary concern is to secure against application-specific attacks, which of the following strategies should the network security engineer consider implementing?

Answers:

- Deploy Layer 4 firewalls on all network edges
- Rely solely on Layer 4 firewalls for internal traffic
- ***Deploy Layer 7 firewalls on all network edges**
- Use Layer 4 firewalls for all internet-facing applications

Explanation:

Layer 7 firewalls, also known as application layer firewalls, have the ability to inspect, control, and often modify application-level data and are effective against application-specific attacks.

Deploying Layer 4 firewalls on all network edges can secure against network-level attacks, but it is not ideal for application-specific attacks as these firewalls mainly operate on the transport layer and do not have deep packet inspection capabilities.

Relying solely on Layer 4 firewalls for internal traffic would miss application-specific vulnerabilities and attacks, as these firewalls do not inspect application-level data.

Layer 4 firewalls are more effective against attacks on the network transport layer, not the application layer.

q_firewalls_ngfw_01_secp8

A network security administrator's responsibilities include enhancing the enterprise's network infrastructure security posture. They deploy a Next Generation Firewall (NGFW) as part of their defense strategy.

The enterprise mixes internal and external services, including a web application and a virtual private network (VPN) for remote access.

Which of the following should the administrator primarily consider when implementing the NGFW to ensure effective security without disrupting normal operations?

Answers:

- ***Deploy the NGFW in inline mode, ensuring it analyzes all traffic while maintaining connectivity.**
- Position the NGFW as a jump server to manage secure access for all network services.
- Set the NGFW to operate in a fail-open mode, ensuring continuous network service even if the firewall fails.
- Use the NGFW as a load balancer, distributing network traffic across multiple servers.

Explanation:

Deploying an NGFW in inline mode enables it to examine all traffic passing through it, identify and mitigate threats, and maintain connectivity without disrupting normal network operations.

An NGFW's primary role is deep packet inspection and threat prevention, not secure access as a jump server.

Although fail-open mode prevents network service interruption if the firewall fails, it may compromise NGFW's primary goal of advanced threat prevention.

A main NGFW function includes advanced threat prevention and deep packet inspection, not load balancing, a technique used to distribute workloads across multiple servers.

q_firewalls_ngfw_02_secp8

A security architect designs a solution to protect the organization's network from advanced threats and provides granular access controls based on user roles.

The organization has a significant volume of TLS-encrypted traffic that needs inspection and wants to integrate the solution with its network directory for role-based content filtering.

Which of the following should the security architect consider the MOST appropriate option?

Answers:

- ***A Next Generation Firewall (NGFW) with Layer 7 application-aware filtering and intrusion prevention system (IPS) functionality**
- A standard stateful firewall with Layer 4 filtering capabilities
- A jump server with enhanced remote access capabilities
- A Web Application Firewall (WAF) designed primarily to protect web applications from targeted attacks

Explanation:

An NGFW with Layer 7 application-aware filtering and IPS functionality can inspect Transport Layer Security (TLS)-encrypted traffic and integrate with network directories for role-based content filtering, meeting the organization's requirements.

A standard stateful firewall with Layer 4 filtering provides basic packet filtering but lacks application-aware filtering at Layer 7 or integration with network directories for role-based content filtering.

A jump server provides secure access to another network segment but lacks advanced threat protection or application-aware filtering required by the organization.

A WAF protects web applications from targeted attacks but does not offer holistic protection or role-based access controls sought by the organization.

q_firewalls_ngfw_utm_secp8

The chief information security officer (CISO) at a medium-sized healthcare company conducts an audit of the company's current security infrastructure.

The company has Next Generation Firewalls (NGFWs) deployed at all external network boundaries, and the CISO is evaluating the possibility of supplementing or replacing the NGFWs with Unified Threat Management (UTM) devices.

If the primary concern is to increase the network's security without introducing significant management complexity, which of the following strategies should the CISO consider implementing?

Answers:

- Replace all NGFWs with UTM devices.
- Deploy UTM devices alongside the NGFWs, with both sets of devices fully active.
- Switch off NGFWs and deploy UTM devices, but only activate UTM when detecting a threat.
- ***Implement UTM devices internally and maintain NGFWs at network boundaries.**

Explanation:

The correct answer is implementing UTM devices internally and maintaining NGFWs at network boundaries. Organizations actively create a balance between enhanced security and manageable complexity when they deploy Unified Threat Management devices internally while also maintaining Next Generation Firewalls at network boundaries.

By replacing NGFWs with UTM devices, organizations actively boost the variety of security features, but this action also introduces significant management complexity due to the increased features that UTM devices have to manage.

Deploying UTM devices alongside the NGFWs, with both sets of devices fully active, does not provide a complete picture of the architecture of implementing UTM devices internally and maintaining NGFWs at network boundaries.

Switching off NGFWs and deploy UTM devices, but only activating UTM devices when detecting a threat does not provide the balance needed between enhanced security and manageable complexity when seeking to increase your network's security.

q_firewalls_packet_01_secp8

Which of the following is a firewall function?

Answers:

- ***Packet filtering**
- FTP hosting
- Encrypting
- Frame filtering

Explanation:

Firewalls often filter packets by checking each packet against a set of administrator-defined criteria. If the packet is not accepted, it is simply dropped.

q_firewalls_packet_02_secp8

You have just installed a packet-filtering firewall on your network.

Which options are you able to set on your firewall? (Select three.)

Answers:

- ***Source address of a packet**
- ***Port number**
- ***Destination address of a packet**
- Sequence number
- Acknowledgement number
- Digital signature
- Checksum

Explanation:

A packet-filtering firewall makes decisions about which network traffic to allow by examining information in the IP packet header, such as source and destination addresses, ports, and service protocols.

Sequence number, acknowledgement number, digital signature, and checksum are information that a packet-filtering firewall does not check by default to make decisions about allowing network traffic through the firewall.

q_firewalls_ports_secp8

When designing a firewall, what is the recommended approach for opening and closing ports?

Answers:

- ***Close all ports; open only ports required by applications inside the network.**
- Open all ports; close ports that expose common network attacks.
- Close all ports; open ports 20, 21, 53, 80, and 443.
- Close all ports.
- Open all ports; close ports that show improper traffic or attacks in progress.

Explanation:

When designing a firewall, the recommended practice is to close all ports and then only open those ports that allow the traffic that you want to allow inside the firewall or the private network.

Ports 20, 21, 53, 80, and 443 are common ports that are opened, but the exact ports you open depends on the services provided inside the firewall.

q_firewalls_stateful_multilayer_secp8

A network administrator at an international baked goods corporation is configuring the company's security infrastructure.

The company has recently had issues with raw Transmission Control Protocol (TCP) packets over open ports by malware, and the administrator needs to be able to inspect packet contents to ensure the application protocol matches the port. The company wants session-state tracking enabled and the ability to block malicious attempts to start bogus sessions.

Which of the following devices should the network administrator focus on implementing?

Answers:

- ***Stateful multilayer inspection firewall**
- Stateful inspection layer 4 firewall
- Stateless packet filtering firewall
- Bridged firewall

Explanation:

A stateful inspection application-aware firewall can inspect the contents of application packets and verify the protocol-port match. It can also track the state of sessions and block bogus sessions.

Layer 4 firewalls operate at the transport layer and can track established connections. However, it cannot verify application protocols like the network administrator requires.

Stateless packet filtering firewalls do not preserve information about network sessions, analyzing packets only in isolation. It does not track session states or verify application protocols.

While a bridged firewall can inspect traffic passing between two nodes and works like a switch, it does not offer the ability to inspect the contents of packets at layer 7.

q_firewalls_stateful_secp8

Which of the following BEST describes a stateful inspection?

Answers:

- Designed to sit between a host and a web server and communicate with the server on behalf of the host.
- ***Determines the legitimacy of traffic based on the state of the connection from which the traffic originated.**
- Offers secure connectivity between many entities and uses encryption to provide an effective defense against sniffing.
- Allows all internal traffic to share a single public IP address when connecting to an outside entity.

Explanation:

Stateful firewalls, also referred to as stateful multilayer firewalls, determine the legitimacy of traffic based on the state of the connection from which the traffic originated. The stateful firewall maintains a state table that tracks the ongoing record of active connections.

A virtual private network (VPN) is a network that provides secure access to a private network through a public network or the internet. Virtual private networks offer secure connectivity between many entities, both internally and remotely. Their use of encryption provides an effective defense against sniffing.

Network Address Translation (NAT) separates IP addresses into two sets. This technology allows all internal traffic to share a single public IP address when connecting to an outside entity.

A firewall can be implemented on circuit-level gateways or Application-level gateways. Both of these firewall designs sit between a host and a web server and communicate with the server on behalf of the host. They can also be used to cache frequently accessed websites for faster web page loading.

q_firewalls_stateless_secp8

Which of the following are characteristics of a basic packet-filtering firewall? (Select two.)

Answers:

- Stateful
- ***Stateless**
- Filters based on URL
- Filters based on sessions
- ***Filters IP address and port**

Explanation:

A packet-filtering firewall makes decisions about which network traffic to allow by examining information in the IP packet header, such as source and destination addresses, ports, and service protocols. A packet-filtering firewall is considered a stateless firewall because it examines each packet and uses rules to accept or reject each packet without considering whether the packet is part of a valid and active session.

A circuit-level proxy or gateway makes decisions about which traffic to allow based on virtual circuits or sessions. A circuit-level proxy is considered a stateful firewall because it keeps track of the state of a session.

Application-level gateways filter on Application layer data, which might include data such as URLs within an HTTP request.

q_firewalls_waf_01_secp8

The security team in a financial organization identified a zero-day vulnerability attack that enables cross-site scripting (XSS) attacks on its internal web portal. The chief information security officer (CISO) instructs the team to take immediate action.

Which action MOST effectively minimizes the threat from the zero-day vulnerability and the potential XSS attacks?

Answers:

- ***Implement a web application firewall (WAF).**
- Upgrade the hardware of the server.
- Encourage staff to change their passwords.
- Restrict the number of login attempts.

Explanation:

Implementing a WAF directly addresses the zero-day vulnerability and XSS attacks by inspecting incoming traffic and blocking suspicious requests.

Upgrading the server hardware might improve overall system performance but does not address software vulnerabilities like XSS.

Encouraging staff to change passwords is generally a good practice in maintaining security, but it does not directly help in preventing XSS attacks. XSS attacks exploit vulnerabilities in web applications to inject malicious scripts, which execute in the context of the victim's session.

Restricting login attempts is a common method used to mitigate brute-force attacks, where an attacker tries multiple combinations to guess a password and does not prevent XSS attacks.

q_firewalls_waf_02_secp8

A newly established e-commerce company experienced increased web-based attacks on its online shopping platform. As a result, the company installed a Web Application Firewall (WAF) to enhance its security infrastructure.

What primary function should the network security manager ensure the WAF is performing to protect the online platform from the MOST common types of web-based threats, such as Cross-site Scripting (XSS), Structured Query Language (SQL) Injection, and Cross-site Request Forgery?

Answers:

- Monitor traffic and block DDoS attacks
- Inspect HTTPS traffic
- ***Validate input and output**
- Encrypt data in transit

Explanation:

A WAF primarily validates input and output. It safeguards against web-based threats by scrutinizing the data sent and received from the web application to ensure compliance with defined security rules.

A WAF assists in mitigating a distributed denial-of-service (DDoS) attack, but its main function does not include handling DDoS attacks. A more comprehensive network security infrastructure manages DDoS attacks.

Though inspecting HTTPS traffic contributes to threat identification, it aligns more with a network-based firewall or an intrusion prevention system function than a WAF.

While encrypting data in transit is crucial to protect sensitive data, it relates more to using protocols such as transport layer security or Secure Sockets Layer than being a primary function of a WAF.

5.5 Virtual Private Networks

As you study this section, answer the following questions:

- What are three ways a Virtual Private Network (VPN) can be implemented?
- What is a VPN concentrator?
- What function do VPN endpoints provide?
- What is the difference between full tunnel and split tunnel?
- What are three types of protocols used by a VPN?
- How does a transport layer security (TLS) VPN work?

In this section, you will learn to:

- Configure a VPN.
- Configure a VPN client.
- Configure a remote access VPN.
- Configure a VPN connection iPad.

The key terms for this section include:

Term	Definition
Virtual Private Network	A remote access connection that uses encryption to securely send data over an untrusted network.
Tunneling	The practice of encapsulating data from one protocol for safe transfer over another network such as the Internet.
Point-to-Point Tunneling Protocol (PPTP)	A early tunneling protocol developed by Cisco and Microsoft to support VPNs over PPP and TCP/IP. PPTP is highly vulnerable to password cracking attacks and considered obsolete.
Layer 2 Forwarding (L2F)	A tunneling protocol developed by Cisco to establish virtual private network connections over the internet.
Internet Protocol Security (IPsec)	Network protocol suite used to secure data through authentication and encryption as the data travels across the network or the Internet.

Secure Sockets Layer (SSL)	A well-established protocol to secure IP protocols, such as HTTP and FTP. And can also be used to secure other application protocols and as a virtual private networking (VPN) solution.
Transport Layer Security (TLS)	Security protocol that uses certificates for authentication and encryption to protect web communications and other application protocols.

This section helps you prepare for the following certification exam objectives:

Exam	Objective
TestOut Security Pro	2.2 Harden Network Devices 2.2.3 Configure and Access a Virtual Private Network (VPN)
CompTIA Security+ SY0-701	3.2 Given a scenario, apply security principles to secure enterprise infrastructure. • Secure communication/access ○ Virtual private network (VPN)

5.5.1 Virtual Private Networks (Lesson Video)

Transcript:

A virtual private network (VPN) uses encryption to send data securely over an untrusted network. The high cost of dedicated WAN connections was one of the mains reasons for VPNs to be used by organizations.

A VPN takes advantage of an existing internet connection to communicate securely between devices. Let's see how this is done.
VPNs provide a secure internet connection between locations by encrypting packets in transit. A VPN uses a protocol that tunnels, or encapsulates, each of those packets into a new packet.
Information in the packet header of these encrypted packets routes the information through the internet. On the destination device, the outer wrapping of the packets is removed, and the packet is decryptedâ€"the data is back in its original format.
If an attacker were to intercept packets sent via a VPN, they wouldn't be able to read any of the contents. Only the device on the other end has the appropriate decryption key that allows them to view the packet contents.
Now, there are multiple ways that you can configure a VPN through the internet.
The first way is using a host-to-host VPN. This type of VPN allows an individual host connected to the internet to establish a VPN connection to another host. With a host-to-host connection, both devices need the ability to establish and understand the VPN protocol that's used. Both devices must have the software for encrypting the packets and encapsulating the packets.
Another way is using a site-to-site VPN. With a site-to-site VPN, you have a collection of computers at each location. Each computer in any location is able to communicate securely with any other computer at another location.
Rather than requiring VPN configuration on every single computer, you install a single device, which acts as a gateway server. A VPN gateway is a dedicated VPN device that handles VPN connections, as well as the encryption and decryption of packets sent over the internet.

The nice thing about using a VPN gateway is the protocols and encapsulation method only need to be configured and maintained on a single device for the entire network, instead of on each individual device. It also allows for all traffic between the two sites to be encrypted 100 percent of the time.
The final method is a remote access VPN. In this case, individual hosts on the network can establish a VPN connection to the remote site. In this configuration, the client computer must be able to establish the VPN connection with a special device called a VPN concentrator that sits on the edge of the private network.
VPN concentrators are hardware devices that are dedicated to establishing client connections, as well as encrypting and decrypting VPN packets. Each client is configured with software that allows it to encrypt packets. The VPN concentrator is configured to allow or reject connections from users. It also removes the encryption before forwarding the information to the private network.
Now, VPNs can use a few different methods to establish connections and encrypt traffic. These methods are known as VPN tunneling protocols. The two most commonly used VPN tunneling protocols are IPsec and SSL.
IPsec encrypts contents sent through a tunnel created by another protocol. IPsec is probably one of the most common tunneling encryption mechanisms currently used, and IPsec is actually made up of two different protocols.
The first one is the Authentication Header, or AH. The second one is the Encapsulating Security Payload (ESP). AH is used to authentic the connection, while ESP is used to encrypt the data that's being sent through the connection.
When you implement IPsec, you can use either of these protocols by themselves. For example, if you chose to implement AH only, then your VPN will have authentication, but no encryption. In most cases, you'll want to make sure that your VPN solution using IPsec includes ESP.
IPsec also has two different modes for sending packets through the tunnel. The first way is called transport mode.
With transport mode, IPsec only encrypts each packet's internal data. Everything elseâ€”the destination IP address, the origination IP addressâ€”is all in cleartext.
The second mode is called tunneling mode. In tunneling mode, the entire packet is encrypted. It is then encapsulated in another non-encrypted packetâ€”complete with a new IP headerâ€”and sent over the internet. Tunnel mode is usually the default sending mode for IPsec.
Another protocol that can be used for a VPN connection is SSL. SSL's been around for a long time. It's been used in combination with other protocols, mostly HTTP, in order to secure traffic between two devices.
For example, if you were to go to an online store and purchase a product, more than likely, you're going to use the secure version of HTTPâ€”HTTPSâ€”to protect the credit card information we're sending to the web server.
Well, HTTPS leverages SSL to encrypt the traffic between those two devices. This makes SSL a great option for encrypting other types of connections between devices, such as a VPN connection. SSL requires certificates for identity proof, as well as for encryption.
One of the benefits of using SSL is the fact that it uses port 443. This is really important because most network firewalls in most organizations are already configured to allow HTTPS traffic on this port, so we don't have to make any major firewall changes if we want to deploy an SSL VPN.
There's one more VPN configuration option we need to discuss, and that is the different between split tunnel and full tunnel VPN configurations.
With a split tunnel VPN, only certain types of trafficâ€”for example, traffic destined for a specific IP address rangeâ€”are sent through the VPN connection. All other traffic goes through the internet as normal. This configuration might be good for people who need to access private network resources but still want to access the internet through their own internet, and not through the VPN. It also helps reduce the amount of traffic sent through the VPNâ€”instead of sending all traffic through the VPN, only necessary traffic is sent.
Split tunneling also has something called inverse split tunneling. This is where all traffic is sent through the VPN except for a specific type of traffic, which is routed through the regular internet, unencrypted. The split is inverted, as its name suggests.
The other way you can configure the VPN is to route all traffic through the VPN, regardless of the type of traffic. This is usually the default VPN configuration method.
When you implement a VPN, be sure to select a protocol supported by all of the devices that need to encrypt or encapsulate packets. When you use a VPN through a firewall, make sure you open the necessary ports to allow the VPN traffic through the firewall. In addition, make sure you know which type of VPN connection and configuration is best for your organization.

5.5.2 Configuring a VPN (Demo Video)

Transcript:

In this demonstration,Â we're going to cover how to configure OpenVPN on a pfSense security appliance.Â We're already logged into pfSense on the Dashboard page.

The first thing I'm going to do is to go to System > Package Manager and select Available Packages. I'm going to type in â€˜openvpn' to search for the OpenVPN Client Export package. This will allow us to export our configuration settings to make setting up our clients a lot easier. Click Install and Confirm. This will take about a minute or so to install. Now let's confirm the installation. Success.
Now let's go over to VPN > OpenVPN. We'll select Wizard to get started. In the past, setting up a VPN was a bit complicated, but the wizard makes setting up OpenVPN really quick and easy.
For the type of server, we're going to select Local User Access. We could also pick LDAP or RADIUS if you have those set up, but we don't. Click Next to continue.
Now we need to create a certificate authority. pfSense adds this right in the wizard so you don't have to do it manually somewhere else, which is nice.
For the Descriptive name, I'll just enter in "TestoutCA". I'll leave these next few fields at the default values and go down to Country Code. Here, I'll enter â€˜US'. For State or Province, I'll enter â€˜UT' for Utah. For City, I'm in the wonderful town of â€˜Pleasant Grove'. For Organization, I'll put â€˜TestOut'. Now click on Add new CA to add the Certificate Authority to the server.
Now we must create a new server certificate. We just added the Certificate Authority. Next, we need an actual certificate. For Descriptive name, I'll just put â€˜Testout'. I'll leave everything with the default values. Country Code, State, City, and Organization are all auto-populated with the correct answers, so I'll just click on Create new certificate.
Now let's configure the server information. For our interface, we want to select our WAN. We also have LAN and DMZ. Our WAN is where traffic will typically come from. Our Protocol will be UDP on IPv4 only. You can see we have some other choices in case your setup is different from mine.
Our VPN uses the default port of 1194. We'll enter a description for our VPN and just call it â€˜TestoutVPN'.
We'll leave all the cryptographic settings set to their defaults and skip down to Tunnel Settings.
The first thing we must do is enter some virtual network settings for our tunnel network. This will be a virtual network that our clients and server will use to communicate on. I'm going to enter '10.10.20.0/24'. All my VPN clients will get an IP address of 10.10.20.something with a subnet mask of 255.255.255.0.
Next is our local network. This is the LAN network that your VPN clients will access. My local LAN network is '10.10.10.0/24'.
For concurrent connections, I'll just put in 5. You can enter more or less than that. It just depends on how many VPN users you'll have connecting at one time.
Now, once your users connect, they'll need a DNS server. You could put in a public DNS or local DNS. I'll put in the DNS that my LAN uses, which is '10.10.10.1'. This is also the IP address of my pfSense appliance.
Scroll down and click Next.
Now we need to set up two firewall rules. We need to allow traffic from our VPN clients to our VPN server. We also need to allow traffic from our clients through the VPN to our network. Lucky for us, we don't have to do this manually. OpenVPN understands what we need, and by checking these boxes, OpenVPN will configure those rules for us. Configuring rules is not part of this lesson, but they're certainly a skill you need to know. Click Next to continue. And on this page, click Finish.
Let's review what we've done. We have our interface set to WAN. Our protocol and port are set to UDP on port 1194. Our tunnel network looks good. Our encryption is here. And our description is TestoutVPN.
Now let's head over to System > User Manager and click on Add. I really don't want my admin user to be the same as one of my VPN users, so I'm going to add a different user here to keep them separate. For the username, I'll enter â€˜danafellows'. I'll enter my password and confirm it. I'll just put Dana for the full name. Click Save.
Everything looks good, and that's all I need to do here.
I'll go back up to VPN > OpenVPN, come down here, and click on the edit icon. For some reason, our server mode changes to Remote Access SSL plus TLS, but we're using Remote Access (User Auth), so we need to confirm that and change it back if needed. It looks like we do, in fact, need to change that. I'll scroll down to the bottom and click on Save.
Now it's time to download the client configuration. We'll go to Client Export. On the next page, scroll down to our list of OpenVPN client configuration options. I'll find the one for the Windows Installer and click on it to download the configuration file.
Now I'll copy this over to a machine I have on a different network and install the OpenVPN client.
I'm now on a machine on my DMZ network. I copied the installation file over, and I'll install it now. I'll click Yes to the User Access Control, click Install to continue, and click through all the rest of these to complete the installation process. Click Finish, and finally, click Close.

Now let's double-click to start the OpenVPN client. I'll drag the installation files into the Recycle Bin.
I'll move the OpenVPN client, here on the taskbar, to a spot where we can see it better. Right-click on it and choose Connect. My username is automatically populated, so I'll just enter in my password and check the Save password box. Click OK to connect. I get a message that I'm connected, and my Assigned IP is listed here.
Now, if you're like me, you might ask yourself, "How did the client know how to connect to my OpenVPN server out there on the internet?" Let's take a second to look at the config file. I'll right-click and select Edit Config to open it. It opens in a text file, and here are all the settings that were configured for us. Down here is the IP address of the WAN interface.
Now, you might say, "Hey, that's a private IP address." Yes it is. This is a test network, so I'm actually using a private IP range for my WAN. Let's take a look at that for a minute.
Here's a diagram of my test network. I accessed my pfSense and OpenVPN settings from this client, over here. The configuration is actually here, on the pfSense. The client over on my DMZ network is the one that initiated the connection to the VPN just a second ago. This client can be anywhere on the internet, but for demo purposes, I placed it on my DMZ. Now let's just confirm a few final things before we wrap up.
I'm still on my client on my DMZ. I'm going to open a command prompt to check my IP settings. I'll do an â€˜ipconfig /all' and press Enter. I'll scroll up a bit. Here's the IP address of this machine on the DMZ, 172.16.1.101. That is my IP scheme for the DMZ. Now let's scroll down a bit. Remember, we made our tunnel network 10.10.20.0, and right here is an address from that range that's assigned to us. We saw that a few minutes ago, also right after we connected.
One final thing. I access the pfSense configuration through a web browser. I have it blocked from being accessed externally. But since we're connected to the LAN through this VPN, let's see if we can access it. I'll open my browser, and in the Address field, I'll enter the IP of the pfSense with the LAN address of 10.10.10.1. When I do that, the Sign In page is displayed, confirming that I have access to LAN resources.
That's it for this demo. We configured OpenVPN on pfSense. We installed the client configuration package, set up our certificate, configured OpenVPN server settings, created a user, downloaded and installed the OpenVPN client on a remote host, and confirmed our connection.

5.5.3 Configuring a VPN Client (Demo Video)

Transcript:

In this demonstration, we're going to create a client VPN connection on a Windows 10 system.

There's VPN software built into Windows 10 that works really well. We're going to go down to the Start button and choose the Settings option. Inside the Settings option, notice that there's a category for Network and Internet, and inside of this category, there's a node for VPN. We can create a VPN connection, and we can choose to allow this VPN connection over metered networks.
This means if we're connecting, maybe via cellular, and this is going to be a charge per gigabyte of data that we transfer, we're going to permit the VPN over this type of connection. We'll also permit the VPN while we're roaming with the system by default, so we'll choose the add a VPN connection button, and then we can choose the VPN provider.
Let's say that we're using the built-in functionality of VPNs with Windows as our VPN provider, and we're going to say this is 'CorpNetVPN'. Then we'll provide the IP address or the fully qualified domain name as long as it's registered in your DNS system for the VPN server. This is typically information that you're going to provide your end users so that they can successfully make the VPN connection.
For the VPN type, often, we'll configure it to be automatic, and we'll have given the instructions to this client for how to connect. But notice you can also configure it so that it's preset for the VPN type. A popular option here is IKE version 2. This would be used with IPSec VPN connections, for example.
You can easily use a smart card, a one-time password, a certificate, or a username and password for verification. We'll do a dfellows username and a password that's extra strong. Once the correct information is entered, we'll save it, and now have a CorpNet VPN connection. We can connect at any time we'd like, or we could go in the advanced options and edit the properties of this connection, clear the sign-in info, or specify that we need to use a VPN proxy. This is a device we'd go to for establishing the VPN on our behalf.
We can easily remove any VPN connection that we've created inside of this settings area, provided that we have the appropriate permissions inside of Windows 10.
That's it for this demo. We discussed how easy it is to establish a VPN connection inside of Windows 10.

5.5.4 Configure a Remote Access VPN (Simulation)

Scenario

You work as the IT security administrator for a small corporate network. Occasionally, you and your co-administrators need to access internal resources when you are away from the office. You would like to set up a Remote Access VPN using pfSense to allow secure access.

In this lab, your task is to use the pfSense wizard to create and configure an OpenVPN Remote Access server using the following guidelines:

- Sign in to pfSense using:
  - Username: admin
  - Password: P@ssw0rd (zero)
- Create a new certificate authority certificate using the following settings:
  - Name: **CorpNet-CA**
  - Country Code: **GB**
  - State: **Cambridgeshire**
  - City: **Woodwalton**
  - Organization: **CorpNet**
- Create a new server certificate using the following settings:
  - Name: **CorpNet**
  - Country Code: **GB**
  - State: **Cambridgeshire**
  - City: **Woodwalton**
- Configure the VPN server using the following settings:
  - Interface: **WAN**
  - Protocol: **UDP on IPv4 only**
  - Description: **CorpNet-VPN**
  - Tunnel network IP: **198.28.20.0/24**
  - Local network IP: **198.28.56.18/24**
  - Concurrent Connections: **4**
  - DNS Server 1: **198.28.56.1**
- Configure the following:
  - A firewall rule
  - An OpenVPN rule
- Set the OpenVPN server just created to **Remote Access (User Auth)** .
- Create and configure the following standard remote VPN users:

Username	Password	Full Name
blindley	L3tM31nNow	Brian Lindley
jphillips	L3tM31nToo	Jacob Phillips

Explanation

While completing this lab, use the following information:

- Create and configure the following standard remote VPN users:

Username	Password	Full Name
blindley	L3tM31nNow	Brian Lindley
jphillips	L3tM31nToo	Jacob Phillips

Complete this lab as follows:

1. Sign in to the pfSense management console.
    a. In the Username field, enter **admin** .
    b. In the Password field, enter **P@ssw0rd** (zero).
    c. Select **SIGN IN** or press **Enter** .
2. Start the VPN wizard and select the authentication backend type.
    a. From the pfSense menu bar, select **VPN > OpenVPN** .
    b. From the breadcrumb, select **Wizards** .
    c. Under *Select an Authentication Backend Type* , make sure **Local User Access** is selected.
    d. Select **Next** .
3. Create a new certificate authority certificate.
    a. For Descriptive Name, enter **CorpNet-CA** .
    b. For Country Code, enter **GB** .
    c. For State, enter **Cambridgeshire** .
    d. For City, enter **Woodwalton** .
    e. For Organization, enter **CorpNet** .
    f. Select **Add new CA** .
4. Create a new server certificate.
    a. For Descriptive Name, enter **CorpNet** .
    b. Verify that all of the previous changes (Country Code, State/Providence, and City) are the same.
    c. Use all other default settings.
    d. Select **Create new Certificate** .
5. Configure the VPN server.
    a. Under General OpenVPN Server Information:
        - Use the *Interface* drop-down menu to select **WAN** .
        - Verify that the Protocol is set to **UDP on IPv4 only** .
        - For Description, enter **CorpNet-VPN** .
    b. Under Tunnel Settings:
        - For Tunnel Network, enter **198.28.20.0/24** .
        - For Local Network, enter **198.28.56.18/24** .
        - For Concurrent Connections, enter **4** .
    c. Under Client Settings, in DNS Server1, enter **198.28.56.1** .
    d. Select **Next** .
6. Configure the firewall rules.
    a. Under *Traffic from clients to server,* select **Firewall Rule** .
    b. Under *Traffic from clients through VPN* , select **OpenVPN rule** .
    c. Select **Next** .
    d. Select **Finish** .
7. Set the OpenVPN server just created to **Remote Access (User Auth)** .
    a. For the WAN interface, select the **Edit Server** icon (pencil).
    b. For Server mode, use the drop-down and select **Remote Access (User Auth)** .
    c. Scroll to the bottom and select **Save** .
8. Configure the following Standard VPN users.
    a. From the pfSense menu bar, select **System > User Manager** .

b. Select **Add** .
c. Configure the User Properties as follows:
    - Username: ***Username***
    - Password: ***Password***
    - Full name: ***Fullname***
d. Scroll to the bottom and select **Save** .
e. Repeat steps 8b-8d to create the remaining VPN users.

5.5.5 Configure a VPN Connection iPad (Simulation)

Scenario

You work as the IT security administrator for a small corporate network. You recently set up the Remote Access VPN feature on your network security appliance to provide you and your fellow administrators with secure access to your network. You are currently at home and would like to connect your iPad to the VPN. Your iPad is connected to your home wireless network.

In this lab, your task is to:

- Add an IPSec VPN connection using the following values:

  This can be added by selecting **Settings** > **General** > **VPN** .

Parameter	Value
Description	**CorpNetVPN**
Server	**198.28.56.22**
Account	**mbrown**
Secret	**asdf1234$**

- Turn on the VPN.
- Verify that a connection is established. The password for mbrown is **L3tM31nN0w** (0 = zero).

Explanation

Complete this lab as follows:

1. Verify your connection to the Home-Wireless network.
    a. Select **Settings** .
    b. Select **Wi-Fi** .
    From the right, notice that you are connected to the Home-Wireless network.
2. Add and configure a VPN.
    a. From the left menu, select **General** .
    b. From the right menu, select **VPN** .
    c. Select **Add VPN Configuration** .

d. Select **IPSec** .
e. Configure the IPSec options as follows:
- Description: **CorpNetVPN** .
- Server: **198.28.56.22**
- Account **: mbrown**
- Secret: **asdf1234$**

f. In the upper right, select **Save** .

3. Connect to the VPN just created.
a. Under VPN Configuration, slide Not Connected to **ON** .
b. When prompted, enter **L3tM31nN0w** (0 = zero) as the password.
c. Select **OK** .

5.5.6 Configure Remote Access, non VPN (Demo Video)

Transcript:

Remote access is a method that allows you to connect to a computer remotely from another computer. This could be useful if you're logging into your computer at home while you're away, helping a family member, or just requiring access to a server. Some of you may be familiar with a VPN, which stands for Virtual Private Network. This is another means of connecting to a remote network when you're physically not there. These connections require more knowledge to set up, but the non-VPN method we're showing you today doesn't.

To get started, we'll open our web browser and type in remotedesktop.google.com. We'd like to access my computer, so let's click on this option here. You'll be required to have a Google account. We already have one, so we're just going to log in. First, we need to provide our email, and after that, input our password. We're not worried about saving the password or this extra pop-up down here, so we'll make these go away. On the left-hand side, we have three options: Remote Access, Remote Support, and Set up via SSH. Remote Access is for accessing another PC, something you'd set up. Remote Support would be for helping someone else, where they'd need to download a link and provide you with a code. The third option is to set up an SSH connection to a Windows or Linux Computer.
We're going to walk through the setup for remote access. First, we must ensure we're on the computer requiring remote access and then download this link here. It will download an extension that can be used by both Chrome and Edge, as they're built on the same platform. It may take a bit for this to download, so we're going to fast-forward. Now, you can see the MSI file is downloaded. All we have to do is click Accept & Install. This will start the installation process. The window should pop up to show us where the MSI file was downloaded. Once executed, it will prompt to close some applications before it can be installed. Our install is done, so we can close this window.
Now that we have Chrome Remote Desktop installed, we can name the PC we are setting up. By default, it grabs the hostname of the computer. If your hostname wasn't set up previously, you may see a mix of letters and numbers instead of Office-PC like this one. We're going to click Next. For security purposes, you'll be required to set up a PIN. I'm going to set this and then confirm it for a second time. After clicking Start, we should be able to accept one final UAC prompt, and then our Office-PC should be ready to go. You'll notice it says Offline; however, when you refresh the web browser, it's now Online. Now, let's try connecting to this PC from another PC.
Okay, we're on our other PC where Chrome Remote Desktop isn't installed. Let's navigate to remotedesktop.google.com and click Access my computer. Login with your previously set up credentials. Once done, we'll see the main screen for our remote desktop menu. In the middle, you can see the computer we just set up for remote access. Let's give it a go and select it. After that, you'll be prompted for a PIN. You can choose to remember it on this device; however, if you're focused on security, you can choose not to remember it.
Great, it looks like our remote connection worked. We have access to the desktop and can do everything on it just like you'd be sitting at this desk, whether it's just surfing the internet or even launching different applications, like system information.
That's it for this demo. In this demo, we showed you how you can leverage a way to connect to your PC remotely without using a VPN.

5.5.7 Virtual Private Network Facts

This lesson covers the following topics:

- VPN basics
- VPN and wireless networks

VPN Basics

A virtual private network (VPN) is a remote-access connection that uses encryption to securely send data over an untrusted network. By using a VPN, you can take advantage of an existing internet connection to securely communicate between devices. When working with VPNs, consider the following:

- A VPN provides an alternative to:
  - WAN connections.
  - Connections that use telephone lines and a remote access server.
- VPNs work by using a Tunneling Protocol that encrypts packet contents and encapsulates those packets.
  - The encapsulated packets are routed through the internet using the information in the packet header.
  - When the packet reaches the destination device, the outer wrapping encapsulating the packets and the encryption is removed.
  - Only the destination device is allowed to remove the wrapping and restore the packet to its original form.
- The following are two styles of VPN tunnels commonly used:
  - Full tunnel, which routes all of a user's network traffic through the VPN tunnel. This can sometimes send traffic that is not necessary.
  - Split tunnel, which routes only certain types of traffic, usually determined by destination IP address, through the VPN tunnel. All other traffic is passed through the normal internet connection.
- VPNs can be implemented in the following ways:
  - A host-to-host VPN allows an individual host connected to the internet to establish a VPN connection to another host on the internet. Both devices must be configured for a VPN connection and have the software to encrypt and encapsulate the packets.
  - A site-to-site VPN uses routers on the edge of each site. The routers are configured for a VPN connection and encrypt and decrypt the packets being passed between the sites. With this configuration, individual hosts are unaware of the VPN.
  - A remote-access VPN uses a server (called a VPN concentrator) configured to accept VPN connections from individual hosts.
    - The VPN concentrator is located on the edge of a network.
    - The VPN concentrator establishes multiple connections with multiple hosts.
    - The individual hosts must be able to establish a VPN connection.
    - The hosts can access resources on the VPN server or the private network using the VPN connection.
  - An always-on VPN employs the concept that a user is always on the VPN, whether physically within the LAN or remotely. There is no turning it on or off. All traffic is basically fully tunneled.
- Tunnel endpoints are devices that can encrypt and decrypt packets. When you create a VPN, you establish a security association between the two tunnel endpoints. These endpoints create a secure virtual communication channel. Only the destination tunnel endpoint can unwrap packets and decrypt the packet contents.
- Routers use the decrypted packet headers to deliver the packet to the destination device. Intermediate routers along the path cannot read the encrypted packet contents.

When implementing a VPN, be sure to:

- Select a protocol that is supported by all devices that need to encrypt and encapsulate packets.
- Open the appropriate ports to allow VPN traffic through the firewall.

VPN and Wireless Networks

VPNs can also be used to help secure connections made over open wireless networks. Many establishments, such as airports, hotels, and restaurants, provide unsecured public Wi-Fi access. Because encryption is not used to secure the wireless connection, many users are hesitant to use these networks. In most cases, this hesitancy is warranted. However, it is generally considered acceptable to use a VPN connection to securely transfer data over an open Wi-Fi network. As long as strong tunneling ciphers and protocols are used, the VPN provides sufficient encryption to secure the connection even though the wireless network itself is not encrypted. It is recommended that you use IPsec or SSL to secure the VPN because these protocols are relatively secure. Avoid using PPTP with MS-CHAPv2 as this configuration setup is no longer considered secure.

If you are using a VPN over an open wireless network and need to access a secure website, be sure your browser's HTTPS requests go through the VPN connection. To conserve VPN bandwidth and improve latency, many VPN solutions automatically reroute web browsing traffic through the client's default network connection instead of through the VPN tunnel. This behavior would result in HTTP/HTTPS traffic being transmitted over the insecure open wireless network instead of through the secure VPN tunnel.

5.5.8 VPN Protocol Facts

This lesson covers the following topics:

- VPN Tunneling Protocol
- Transport Layer Security Tunneling
- Internet Protocol Security Tunneling
- Secure Communication and Access

VPN Tunneling Protocol

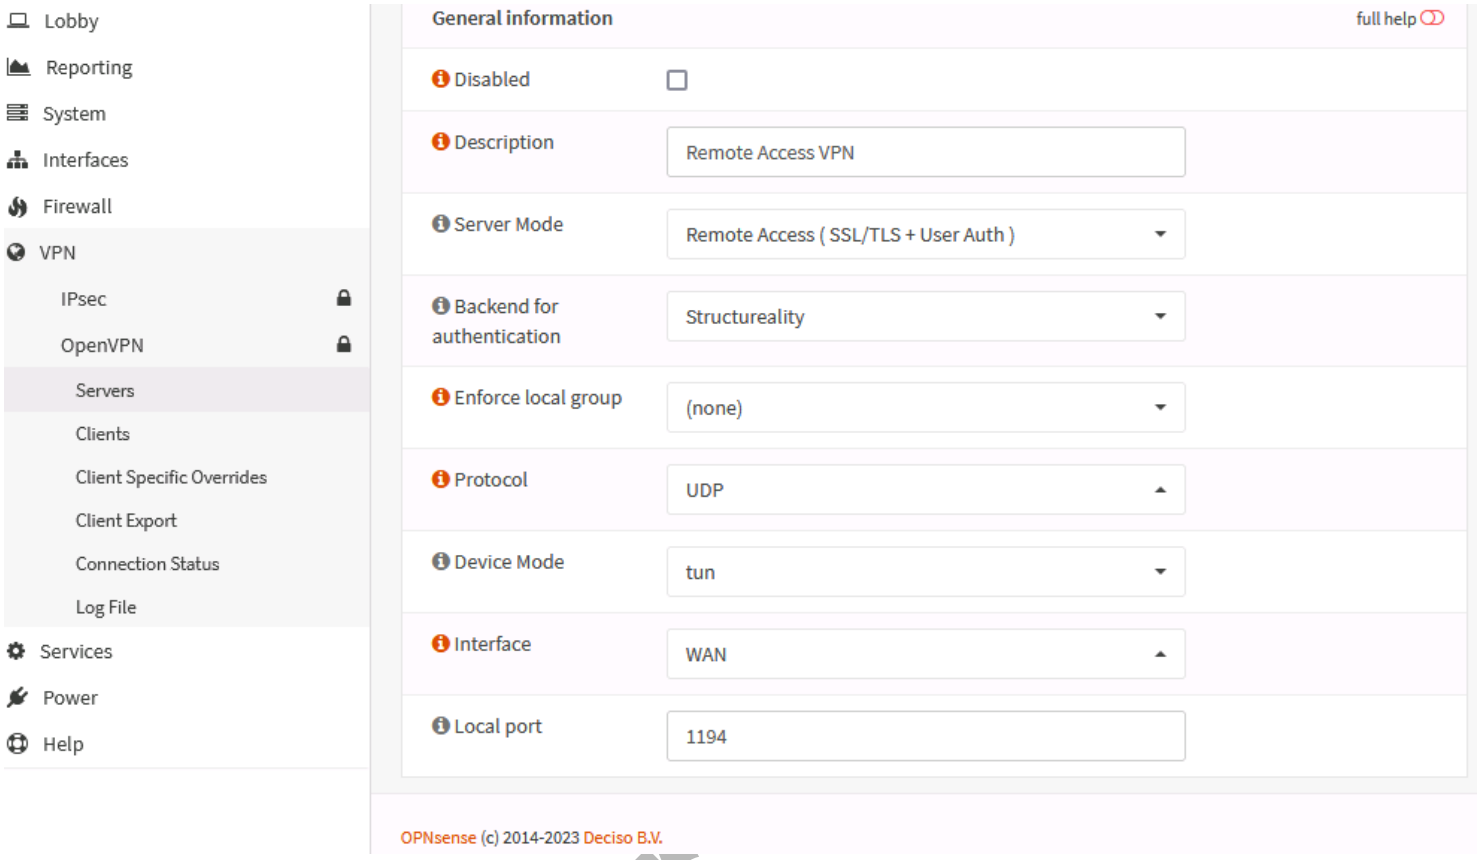
A VPN can use a Tunneling Protocol that encrypts packet contents and wraps them in an unencrypted packet. The Tunneling Protocol (also referred to as the VPN Protocol) identifies the methods that devices use to establish the VPN connection and encrypt the data. The three types of protocols used by VPNs are:

- Carrier Protocol (such as IP).
- Tunneling Protocol (such as PPTP or L2TP).
- Passenger Protocol (for the data being transmitted).

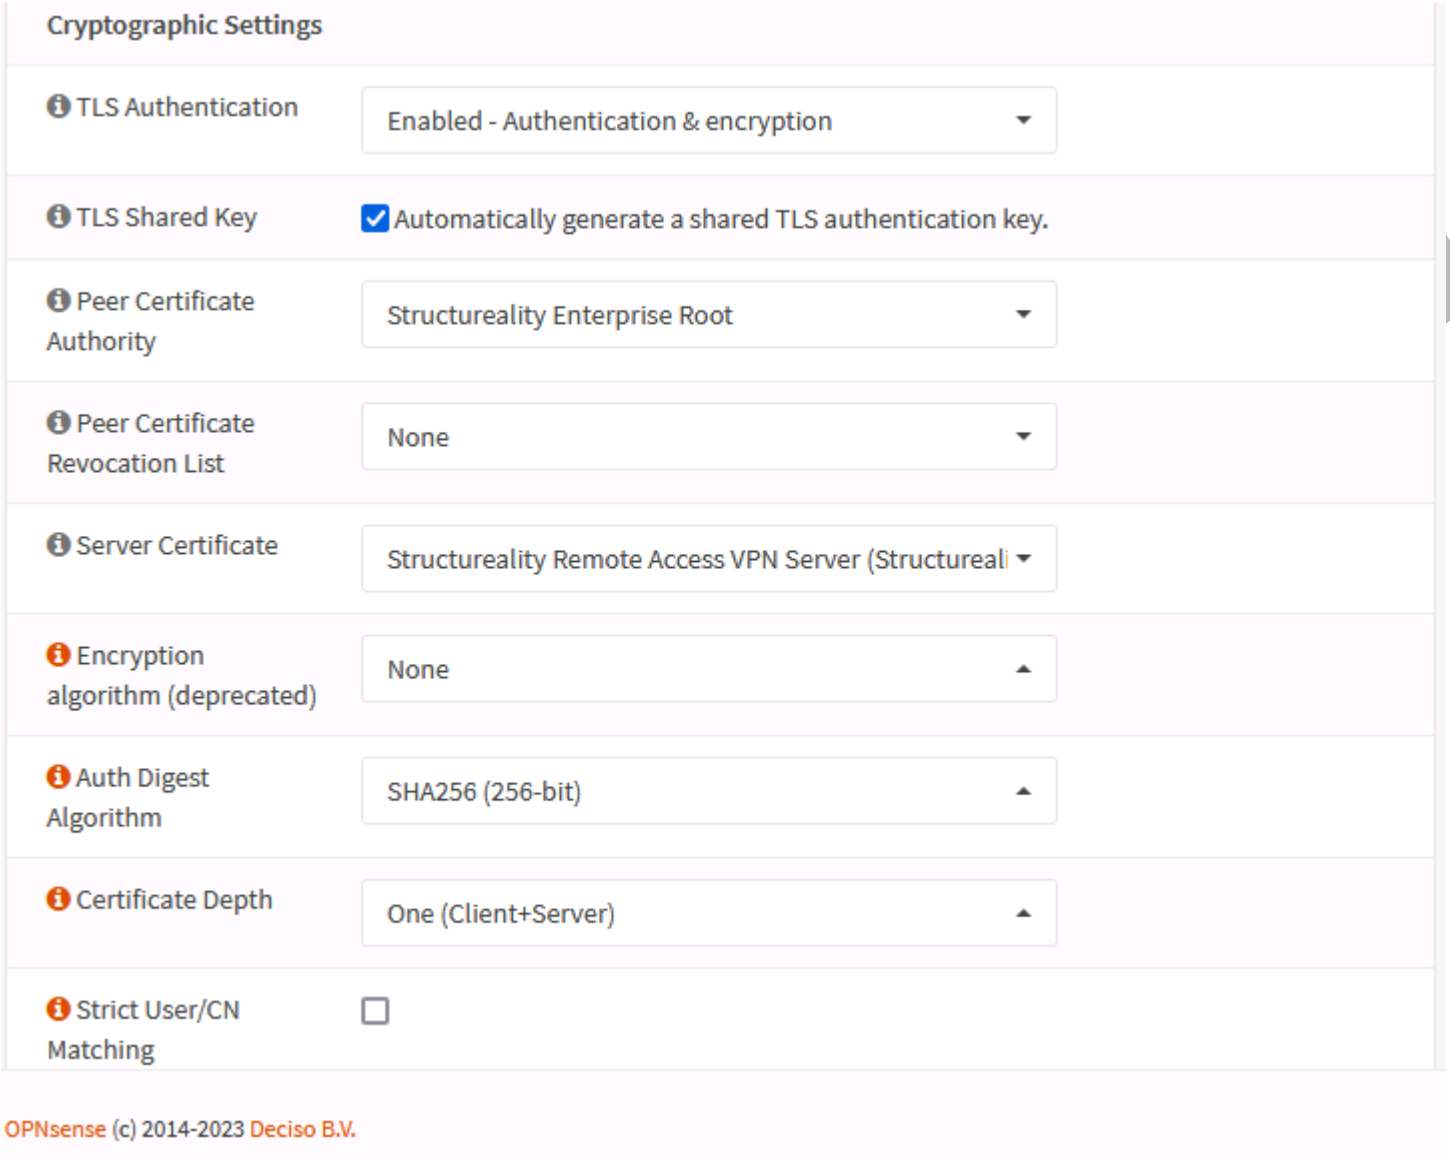
Many networks make use of a piece of hardware called a VPN concentrator. VPN concentrators are advanced routers that can create and maintain many secure connections to the network through VPN tunnels.

Transport Layer Security Tunneling

A transport layer security (TLS) VPN means the client connects to the remote access server using digital certificates. The server certificate identifies the VPN gateway to the client. Optionally, the client can also be configured with its own certificate. This allows for mutual authentication, where both server and client prove their identity to one another. TLS creates an encrypted tunnel for the user to submit authentication credentials. These would normally be processed by a RADIUS server. Once the user is authenticated and the connection is fully established, the VPN gateway tunnels all communications for the local network over the secure socket.



Configuring an OpenVPN server in the OPNsense security appliance. This configuration creates a remote access VPN. Users are authenticated via a RADIUS server on the local network. (Screenshot courtesy of OPNsense)



A TLS VPN can use either TCP or UDP. UDP might be chosen for marginally superior performance, especially when tunneling latency-sensitive traffic such as voice or video. TCP might be easier to use with a default firewall policy. TLS over UDP is also referred to as Datagram TLS (DTLS).

It is important to use a secure version of TLS. The latest version at the time of writing is TLS 1.3. TLS 1.2 is also still supported. Versions earlier than this are deprecated.

Internet Protocol Security Tunneling

Transport Layer Security is applied at the application level. Internet Protocol Security (IPsec) operates at the network layer of the OSI model (layer 3). This means that it can be implemented without having to configure specific application support and that it incurs less packet overhead.

There are two core protocols in IPsec, which can be applied singly or together, depending on the policy:

- Authentication Header (AH)—performs a cryptographic hash on the whole packet, including the IP header, plus a shared secret key (known only to the communicating hosts), and adds this value in its header as an

Integrity Check Value (ICV). The recipient performs the same function on the packet and key and should derive the same value to confirm that the packet has not been modified. The payload is not encrypted so this protocol does not provide confidentiality.

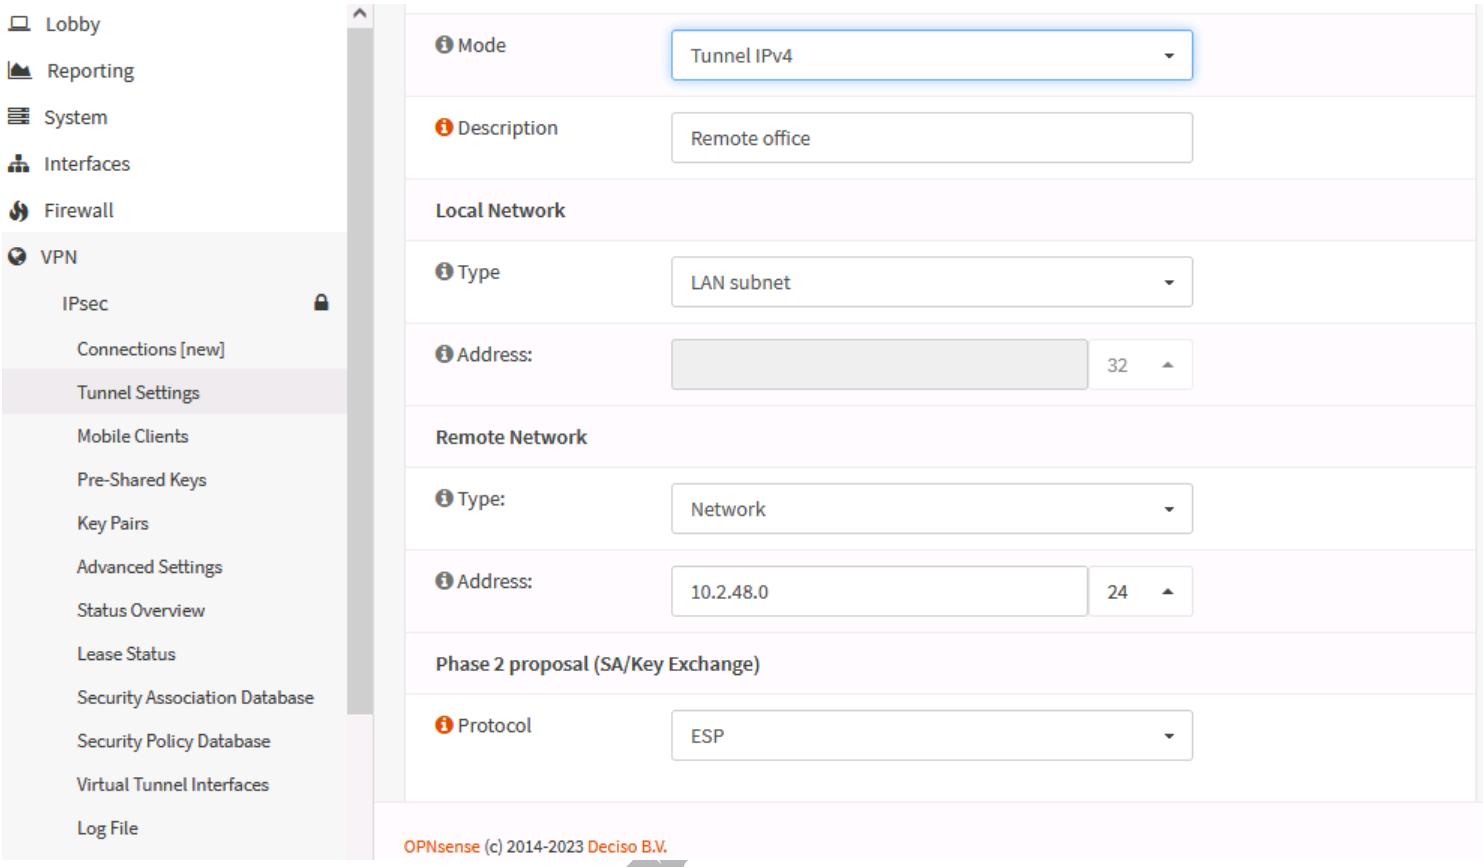
- Encapsulating Security Payload (ESP) can be used to encrypt the packet rather than simply calculating an ICV. ESP attaches three fields to the packet: a header, a trailer (providing padding for the cryptographic function), and an Integrity Check Value. Unlike AH, ESP excludes the IP header when calculating the ICV.

IPsec can be used in two modes:

- Transport mode—is used to secure communications between hosts on a private network. When ESP is applied in transport mode, the IP header for each packet is not encrypted, just the payload data. If AH is used in transport mode, it can provide integrity for the IP header.

- Tunnel mode—is used for communications between VPN sites across an unsecure network. With ESP, the whole IP packet (header and payload) is encrypted and encapsulated as a datagram with a new IP header. AH has no use case in tunnel mode, as confidentiality is usually required.

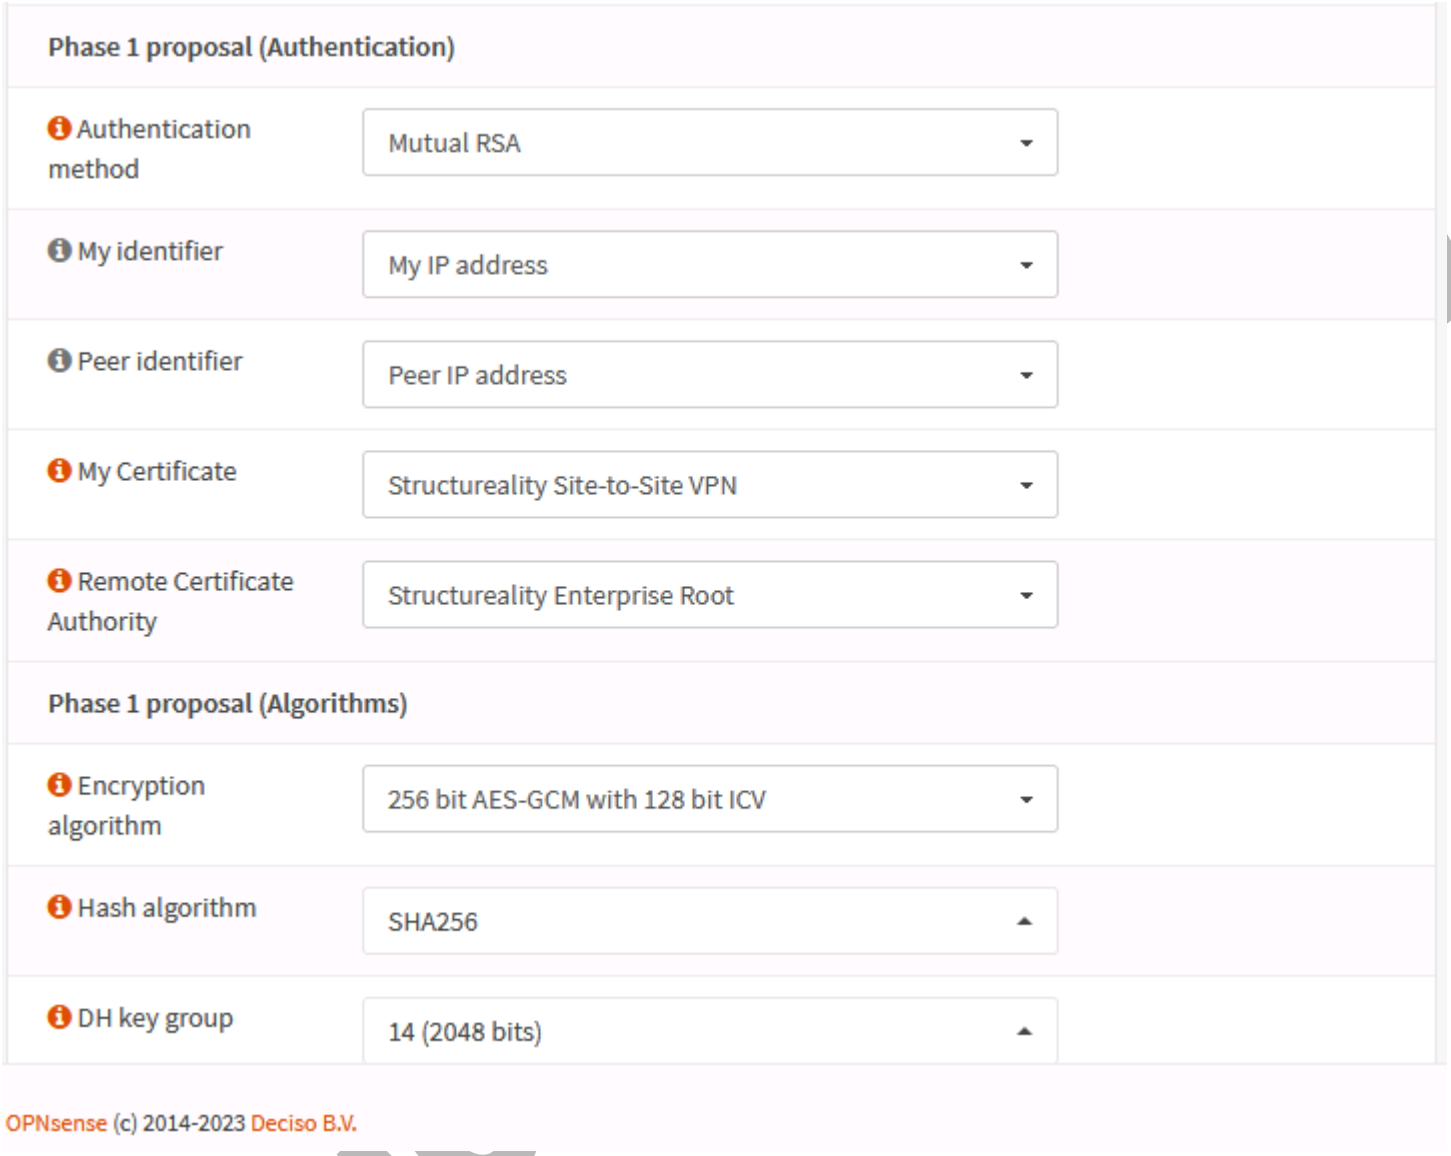
IPsec datagram using ESP in tunnel mode.



Configuring a site-to-site VPN using IPsec tunneling with ESP encryption in the OPNsense security appliance. (Screenshot courtesy of OPNsense)

Each host or router that uses IPsec must be assigned a policy. An IPsec policy sets the authentication mechanism and also the use of AH/ESP and transport or tunnel mode for a connection between two peers.

IPsec's encryption and hashing functions depend on a shared secret. The secret must be communicated to both peers, and the peers must perform mutual authentication to confirm one another's identity. The Internet Key Exchange (IKE) p rotocol implements an authentication method, selects which cryptographic ciphers are mutually supported by both peers, and performs key exchange. The set of properties is referred to as a s ecurity association (SA).



IKE negotiations take place over two phases:

- Phase I establishes the identity of the two peers and performs key agreement using the Diffie-Hellman algorithm to create a secure channel. Two methods of authenticating peers are commonly used:
- Digital certificates —are issued to each peer by a mutually trusted certificate authority to identify one another.
- Pre-shared key (group authentication) —is when the same passphrase is configured on both peers.
- Phase II uses the secure channel created in Phase I to establish which ciphers and key sizes will be used with AH and/or ESP in the IPsec session.

There are two versions of IKE. Version 1 was designed for site-to-site and host-to-host topologies and requires a supporting protocol to implement remote access VPNs. IKEv2 has some additional features that have made the protocol popular for use as a stand-alone remote access client-to-site VPN solution. The main changes are the following:

- Supports EAP authentication methods, allowing, for example, user authentication against a RADIUS server.
- Provides a simple setup mode that reduces bandwidth without compromising security.

- Allows network address translation (NAT) traversal and MOBIKE multihoming. NAT traversal makes it easier to configure a tunnel allowed by a home router/firewall. Multihoming means that a smartphone client with Wi-Fi and cellular interfaces can keep the IPsec connection alive when switching between them.

Secure Communication and Access

A Software-Defined Wide Area Network (SD-WAN) enables organizations to connect their various branch offices, datacenters, and cloud infrastructure over a wide area network (WAN). One of the key advantages of SD-WAN is its ability to provide enhanced security features and considerations. For example, SD-WAN uses encryption to protect data as it travels across the network and can segment network traffic based on priority ratings to ensure that critical data is fully protected.

Additionally, SD-WAN can intelligently route traffic based on the application and tightly integrate with firewalls to provide additional protection against known threats. SD-WAN centralizes the management of network security policies to simplify enforcing security measures across an entire network.

Secure Access Service Edge (SASE) combines the protection of a secure access platform with the agility of a cloud-delivered security architecture. SASE offers a centralized approach to security and access, providing end-to-end protection and streamlining the process of granting secure access to all users, regardless of location. SASE is a network architecture that combines wide area networking (WAN) technologies and cloud-based security services to provide secure access to cloud-based applications and services.

SASE offers several security features to help organizations protect their networks and data as SASE operates under a zero trust security model. SASE incorporates Identity and Access Management (IAM) and assumes all users and devices are untrusted until they are authenticated and authorized. SASE also provides a range of threat prevention features, such as intrusion prevention, malware protection, and content filtering.

5.5.9 Implement Secure Remote Access Protocols

5.5.10 Practice Questions (Section Quiz)

q_vpn_config_secp8

A salesperson in your organization spends most of her time traveling between customer sites. After a customer visit, she must complete various managerial tasks, such as updating your organization's order database.

Because she rarely comes back to your home office, she usually accesses the network from her notebook computer using Wi-Fi access provided by hotels, restaurants, and airports.

Many of these locations provide unencrypted public Wi-Fi access, and you are concerned that sensitive data could be exposed. To remedy this situation, you decide to configure her notebook to use a VPN when accessing the home network over an open wireless connection.

Which key steps should you take when implementing this configuration? (Select two.)

Answers:

- ***Configure the VPN connection to use IPsec**
- Configure the VPN connection to use MS-CHAPv2
- ***Configure the browser to send HTTPS requests through the VPN connection**
- Configure the browser to send HTTPS requests directly to the Wi-Fi network without going through the VPN connection
- Configure the VPN connection to use PPTP

Explanation:

It is generally considered acceptable to use a VPN connection to securely transfer data over an open Wi-Fi network. As long as strong tunneling ciphers and protocols are used, the VPN provides sufficient encryption to secure the connection, even though the wireless network itself is not encrypted. It is recommended that you use IPsec or SSL to secure the VPN, as these protocols are relatively secure. You should also configure the browser's HTTPS requests to go through the VPN connection. To conserve VPN bandwidth and improve latency, many VPN solutions automatically reroute web browsing traffic through the client's default network connection instead of through the VPN tunnel. This behavior would result in HTTP/HTTPS traffic being transmitted over the unsecure open wireless network instead of though the secure VPN tunnel.

Avoid using PPTP with MS-CHAPv2 in a VPN over open wireless configuration, as these protocols are no longer considered secure.

q_vpn_example_secp8

An IT team at a global pharmaceutical company has decided to implement a virtual private network (VPN) for remote employees to securely access internal company resources from home.

Which of the following is a primary reason for this decision?

Answers:

- ***VPNs encrypt and encapsulate all traffic to create a secure tunnel**
- VPNs provide a direct connection to a single machine.
- VPNs provide secure command-line access and file transfer.
- VPNs are designed for managing devices on IP networks.

Explanation:

VPNs create a secure private connection between the remote user's device and the company's internal network, require authentication, and use a network tunnel to encrypt and encapsulate all traffic.

Remote Desktop Protocol (RDP) allows a user to remotely access and control another machine but does not encrypt all traffic or create a network tunnel.

This rationale is characteristic of Secure Shell (SSH), which offers secure, encrypted command-line access and file transfer but does not encapsulate all traffic or create a network tunnel.

Simple Network Management Protocol (SNMP) is a device management protocol for IP networks, not for creating a secure connection for a remote user.

q_vpn_remote_secp8

A group of salesmen would like to remotely access your private network through the internet while they are traveling. You want to control access to the private network through a single server.

Which solution should you implement?

Answers:

- ***VPN concentrator**
- IDS

- IPS
- DMZ

Explanation:

With a remote access VPN, a server on the edge of a network (called a VPN concentrator) is configured to accept VPN connections from individual hosts. Hosts that are allowed to connect using the VPN connection are granted access to resources on the VPN server or the private network.

A demilitarized zone (DMZ), also called a screened subnet, is a buffer network (or subnet) that sits between the private network and an untrusted network (such as the internet). A RADIUS server is used to centralize authentication, authorization, and accounting for multiple remote access servers. However, clients still connect to individual remote access servers.

An intrusion detection system (IDS) is a special network device that can detect attacks and suspicious activity. A passive IDS monitors, logs, and detects security breaches, but it does not take action to stop or prevent an attack. An active IDS (also called an intrusion protection system or IPS) performs the functions of an IDS but can also react when security breaches occur.

q_vpn_secure_secp8

A VPN is primarily used for which of the following purposes?

Answers:

- Allow remote systems to save on long-distance charges
- ***Support secured communications over an untrusted network**
- Allow the use of network-attached printers
- Support the distribution of public web documents

Explanation:

A VPN (virtual private network) is used primarily to support secured communications over an untrusted network. A VPN can be used over a local area network, across a WAN connection, over the internet, and even between a client and a server over a dial-up internet connection.

All of the other items listed in this question are benefits or capabilities that are secondary to this primary purpose.

q_vpn_site_secp8

Which VPN implementation uses routers on the edge of each site?

Answers:

- ***Site-to-site VPN**
- Host-to-host VPN
- Remote access VPN
- Always-on VPN

Explanation:

A site-to-site VPN uses routers on the edge of each site. The routers are configured for a VPN connection and encrypt and decrypt the packets being passed between the sites. With this configuration, individual hosts are unaware of the VPN.

A host-to-host VPN allows an individual host connected to the internet to establish a VPN connection to another host on the internet. Both devices must be configured for a VPN connection and have the software to encrypt and encapsulate the packets.

A remote access VPN uses a server (called a VPN concentrator) configured to accept VPN connections from individual hosts.

An always-on VPN employs the concept that a user is always on the VPN, whether physically within the LAN or remotely. There is no turning it on or off. All traffic is basically fully tunneled.

q_vpn_split_secp8

Which VPN tunnel style routes only certain types of traffic?

Answers:

- Full
- ***Split**
- Site-to-site
- Host-to-host

Explanation:

A VPN split tunnel routes only certain types of traffic, usually determined by destination IP address, through the VPN tunnel. All other traffic is passed through the normal internet connection.

A full VPN tunnel routes all of a user's network traffic through the VPN tunnel. This can sometimes send traffic that is not necessary.

A site-to-site VPN is a VPN implementation that uses routers on the edge of each site.

A host-to-host VPN implementation allows an individual host connected to the internet to establish a VPN connection to another host on the internet.

q_vpn_prot_esp_01_secp8

Which IPSec subprotocol provides data encryption?

Answers:

- SSL
- AES
- AH
- ***ESP**

Explanation:

Encapsulating Security Payload (ESP) Protocol provides data encryption for IPSec traffic.

Authentication Header (AH) provides message integrity through authentication, verifying that data is received unaltered from the trusted destination. AH provides no privacy and is often combined with ESP to achieve integrity and confidentiality.

SSL is standard technology for securing an internet connection by encrypting data sent between a website and a browser. It is not used for IPSec.

The Advanced Encryption Standard (AES) is an algorithm that uses the same key to encrypt and decrypt protected data. However, it is not used by IPSec.

q_vpn_prot_esp_02_secp8

In addition to Authentication Header (AH), IPSec is comprised of what other service?

Answers:

- Encryption File System (EFS)
- Extended Authentication Protocol (EAP)
- Advanced Encryption Standard (AES)
- ***Encapsulating Security Payload (ESP)**

Explanation:

IPsec is comprised of two services. One service is named Authentication Header (AH), and the other named Encapsulating Security Payload (ESP). AH is used primarily for authenticating the two communication partners of an IPsec link. ESP is used primarily to encrypt and secure the data transferred between IPsec partners. IPSec employs ISAKMP for encryption key management.

EFS provides a file system interface, file system access semantics (such as strong consistency and file locking), and concurrently accessible storage for up to thousands of EC2 instances. It is not used with IPSec.

Extensible Authentication Protocol (EAP) is used to pass the authentication information and handles and defines an authentication. It is not used with IPSec.

The Advanced Encryption Standard (AES) is an algorithm that uses the same key to encrypt and decrypt protected data. However, it is not used with IPSec.

q_vpn_prot_ike_ipsec_secp8

A network engineer has the task of creating a remote access solution for a global enterprise. The solution should secure encrypted communication for the company's employees worldwide and detect potential security threats in real time.

Which configuration should the network engineer deploy to meet these requirements?

Answers:

- ***A VPN utilizing IKE and IPSec protocols, combined with an inline intrusion detection system (IDS)**
- A network fortified by 802.1X port security, an Extensible Authentication Protocol (EAP), and a load balancer
- A network equipped with a Next Generation Firewall (NGFW), a Web Application Firewall (WAF), and an intrusion prevention system (IPS) in tap/monitor mode
- A Software-Defined Wide Area Network (SD-WAN) with secure access service edge (SASE) implementation, supplemented by an intrusion prevention system (IPS)

Explanation:

A VPN using internet key exchange and IPSec protocols secures remote access and communication. An inline IDS detects potential security threats in real time.

802.1X port security and EAP provide robust network security but don't address secure remote access. A load balancer manages traffic but doesn't contribute to threat detection.

An NGFW and WAF protect the network and web applications but don't provide secure remote access. An IPS in tap/monitor mode detects intrusions but isn't as effective as an inline system.

SD-WAN with SASE provides secure, scalable cloud-based network architecture but focuses more on optimization than secure remote access. An IPS prevents intrusions but doesn't directly address threat detection or secure remote access.

q_vpn_prot_ike_phases_secp8

Which of the following is commonly used in the first phase of Internet Key Exchange (IKE) negotiations for authenticating the identity of peers?

Answers:

- ***Digital certificates**
- Passwords
- Biometrics
- Security questions

Explanation:

Digital certificates is the correct answer. Digital certificates are commonly used in the first phase of IKE negotiations to authenticate the identity of peers. They provide a way to exchange public keys and contain information about the entity it represents, the entity that issued the certificate, and the digital signature of the issuer.

While passwords can be used in some forms of authentication, they are not typically used in the first phase of IKE negotiations. The use of passwords alone would not provide the level of security required for VPN connections.

Biometric authentication, such as fingerprint or facial recognition, is not used in IKE negotiations. This form of authentication is more commonly used for physical or device access rather than network connections.

Security questions are typically used for resetting passwords or additional layer of authentication, not for the initial authentication of peers in IKE negotiations.

q_vpn_prot_ipsec_01_secp8

Which statement BEST describes IPsec when used in tunnel mode?

Answers:

- ***The entire data packet, including headers, is encapsulated**
- The identities of the communicating parties are not protected
- IPsec in tunnel mode may not be used for WAN traffic
- Packets are routed using the original headers, and only the payload is encrypted

Explanation:

When using IPsec in tunnel mode, the entire data packet, including original headers, is encapsulated. New encrypted packets are created with headers indicating only the endpoint addresses. Tunneling protects the identities of the communicating parties and original packet contents.

Tunneling is frequently used to secure traffic traveling across insecure public channels, such as the internet. IPsec in tunnel mode is the most common configuration for gateway-to-gateway communications.

In transport mode, routing is performed using the original headers; only the packet's payload is encrypted. Transport mode is primarily used in direct host-to-host communication outside of a dedicated IPsec gateway/firewall configuration.

q_vpn_prot_ipsec_02_secp8

A security team in a multinational organization decides to improve the security of their inter-office communications. They agree to use a tunneling protocol that can offer confidentiality, sender authentication, and message integrity.

They need a protocol that operates at the network level.

Which protocol BEST fulfills the team's requirements for securing inter-office communications and operates at the network level?

Answers:

- HTTPS
- SSH
- ***IPSec**
- TLS

Explanation:

Internet Protocol Security (IPSec) best meets the team's requirements by providing confidentiality, sender authentication, and message integrity by functioning at the network level.

Hypertext Transfer Protocol Secure (HTTPS) operates at the application layer, primarily securing communication between web browsers and web servers, but it does not cater to inter-office communications.

Secure Shell (SSH) is a network communication protocol that allows two computers or devices to communicate and share data. However, it is not normally associated with securing inter-office communications.

Transport Layer Security (TLS) is a security protocol designed to facilitate privacy and data security for communications over the Internet, not for inter-office communications.

q_vpn_prot_l2tp_secp8

Which VPN protocol typically employs IPsec as its data encryption mechanism?

Answers:

- PPTP
- ***L2TP**
- PPP
- L2F

Explanation:

L2TP (Layer 2 Tunneling Protocol) is the VPN protocol that typically employs IPsec as its data encryption mechanism. L2TP is the recommended VPN protocol to use on dial-up VPN connections.

PPTP and PPP only support CHAP and PAP for data encryption. L2F offers no data encryption.

q_vpn_prot_sd-wan_secp8

A global enterprise is expanding its infrastructure to handle the increased service demand. The enterprise plans to deploy several load balancers across its geographically distributed data centers as part of the expansion process.

The senior network engineer's responsibilities include designing a secure load-balancing solution that ensures maximum availability, minimizes the attack surface, and provides secure communication between the data centers.

What approach BEST ensures secure and efficient load balancing across geographically distributed data centers?

Answers:

- ***Use a Software-Defined Wide Area Network (SD-WAN) solution along with the load balancers.**
- Deploy load balancers in each data center and secure them using a Layer 7 firewall.
- Implement secure access service edge (SASE) to provide secure and enhanced network connectivity.
- Configure load balancers in fail-closed mode and use a VPN for secure communication.

Explanation:

SD-WAN provides secure, efficient, and flexible load balancing across geographically distributed data centers.

Deploying load balancers in each data center and securing them with a Layer 7 firewall may not be the best solution for secure and efficient load balancing.

SASE provides secure network connectivity but does not directly address the load-balancing requirements of geographically distributed data centers.

Configuring load balancers in a fail-closed mode mitigates the risk of unfiltered traffic but might interrupt service availability. Using a VPN may not be the most efficient solution due to potential latency issues.

q_vpn_prot_tls_01_secp8

The IT department in a large multinational corporation faces challenges managing secure communications for remote desktop connections. The increasing number of remote employees has made it essential to ensure that their remote desktop connections are secure. The IT department is considering various measures to establish secure communication.

Given the challenges the corporation faces, what approach should the IT department adopt to ensure secure communications for remote desktop connections while maintaining the manageability and performance of the enterprise infrastructure?

Answers:

- ***Implement TLS for all remote desktop connections**
- Disable all firewall rules for remote desktop connections
- Establish VPN tunnels for all users without using any encryption protocols
- Enable open access to all remote desktop connections for easy manageability

Explanation:

Transport layer security (TLS) provides secure communication for remote desktop connections by encrypting the data transmitted between the end user and the remote desktop server, reducing the risk of data breaches.

Disabling all firewall rules for remote desktop connections is not a secure practice. It exposes the enterprise infrastructure to potential cyberattacks.

Establishing virtual private network (VPN) tunnels for all users without using any encryption protocols does not secure communications. While VPN tunnels provide a layer of security, the data transmitted is still vulnerable to interception and breaches without encryption.

Enabling open access to all remote desktop connections for easy manageability compromises the security of the enterprise infrastructure. It exposes the enterprise to numerous potential security threats and cyberattacks.

q_vpn_prot_tls_02_secp8

A medium-sized organization implements a secure access service edge (SASE) solution to secure its distributed network. The IT manager wants to protect all data in transit.

Which of the following should the organization implement alongside SASE to achieve this goal?

Answers:

- ***A Transport Layer Security (TLS) protocol to secure data in transit**
- A standalone intrusion detection system (IDS) to monitor network traffic
- A Software-Defined Wide Area Network (SD-WAN) to manage network connectivity
- A Layer 4 firewall to control access to network resources

Explanation:

The Transport Layer Security (TLS) protocol encrypts data in transit, providing an additional layer of security alongside SASE to help to ensure sensitive information remains confidential and protected from unauthorized access.

While an intrusion detection system (IDS) can monitor network traffic for signs of security threats, it doesn't specifically secure data in transit, meaning data could still be vulnerable to interception or tampering.

An SD-WAN can manage network connectivity and optimize traffic routing but does not inherently secure data in transit, so additional measures may be necessary to protect sensitive information.

A Layer 4 firewall controls access to network resources by filtering traffic based on port numbers and protocols, but it does not specifically secure data in transit.

5.6 Network Access Control

As you study this section, answer the following questions:

- How do remediation servers and auto-remediation help clients become compliant?
- What are the security standards NAC uses for evaluation?
- What is an NAC agent? What types of NAC agents are available?
- What are the four steps of the NAC process?

The key terms for this section include:

Term	Definition
Network access control (NAC)	A general term for the collected protocols, policies, and hardware that authenticate and authorize access to a network at the device level.
Bring your own device (BYOD)	Security framework and tools to facilitate use of personally owned devices to access corporate networks and data.

This section helps you prepare for the following certification exam objectives:

Exam	Objective
CompTIA Security+ SY0-701	4.5 Given a scenario, modify enterprise capabilities to enhance security. • Network access control (NAC)

5.6.1 Network Access Control (Lesson Video)

Transcript:

Network Access Control, or NAC, is a process control that prevents unauthorized access and preserves the integrity of a production network. Depending on the configuration, an endpoint must meet certain criteria in order to join the internal network. In this lesson, we'll discuss the components and steps required for an end device to access an internal network.

Before an end device can connect, it must go through several validation checks, and it meet specified criteria. For example, a system may need to be running Windows 10 with update 1907. It may also need to have the latest antivirus latest definitions installed, have Windows firewall enabled, have the latest updates installed, and have automatic updates enabled.
If any of this criteria isn't met, the system belongs on a restricted network. A restricted network has equipment with the software, drivers, and updates you need to retrieve the required settings. Once the system is remediated and receives all the updates and system changes, it's safe for it to join the production network.
Depending on the company's business market, a compliance model may dictate the level of protection and integrity a network system requires. Compliance industries include the medical, defense, and financial sectors. Each one has government-regulated compliance rules.
The basic tenants of NAC include zero-day attack mitigation, role-based controls, traffic encryption, identity management, and policy enforcement. These goals vary widely depending on NAC implementation, configuration, compliance requirements, and industry. To create an effective solution, you have to understand the resources you're protecting and why you're protecting them.
Now, network access control is a process, not a product, although several companies implement a product that uses the NAC process. For example, Cisco has a solution called Identity Services Engine, or ISE, while Microsoft has Network Access Protection, or NAP. Each is a framework that provides protection against unauthorized access or rogue system access to a protected network. The distinction between products is vendor-specific, and so is the implementation.

Before a device can connect to the production network, it must go through a health check. The health check is configured by system management and may include criteria like antivirus software, firewall configurations, and patches. This health check is performed by software designed solely for this purpose.
One way to run this software is using an agent. An agent is a preinstalled software program that performs these health checks at predefined times. One example of how this might work happens when the workstation attempts a connection to the production network. At that time, the agent is activated and goes through its checks to ensure that the workstation meets the minimum requirements to access the production network.
Depending on the vendor, it's also possible to perform health checks on demand. This process is agentless, meaning it doesn't require a permanent agent to be preinstalled. Instead, the required software is downloaded and executed at the workstation when it attempts to connect to the network. Access to the production network is only granted if all the prerequisites are met and the health check passes.
Network Access Control is a policy-driven construct that maintains network integrity using authentication and authorization policies. NAC can be compartmentalized for different types of devices such as Internet of Things, Bring Your Own Device, or vendors and contractors.
NAC defines the prerequisites and identity, or authentication. If a devices meets requirements, NAC provides access to the target information. You can think of NAC as a layered approach to providing network admission and access. Let's see how it works.
The first layer defines the tasks required for authentication. The authentication layer defines all the prerequisites a device must meet to access the network. This criteria is detailed in policies that define minimum requirements for the device, such as anti-malware software, OS type, patch level, and so on.
Keep in mind that the policies may be different for dissimilar types of devices. For instance, a tablet may be required to be managed by an MDM package or have backup and remote wipe enabled. Likewise, an Internet of Things device might be required to use a secure VLAN.
If a device fails authentication, it's forwarded to a remediation network. This network is protected and doesn't have access to any production information or outside areas such as the internet. Instead, the remediation network is preconfigured to contain all the necessary software and procedures to bring a device into compliance. It may have software updates, anti-malware definitions, and other control software. Once a device goes through remediation, it goes through the authentication process again. If it passes, it moves on to the authorization process.
The most secure method for ensuring integrity is a zero-trust access model. This is the concept of least privilege, or implicit deny all. With this model, users or devices are only given the permissions they require to do their jobsâ€“ no more, no less.
The authorization process looks at the authentication information and applies the policies you choose. After the device goes through the authorization process, it's granted access to the production network. This process isn't easy to set up, and it's often set up incorrectly. Several policies must be put into place, and boundary networks must be configured. Everything from connectivity devices to routing and switching must comply with the necessary logic to ensure that this process works. While difficult, it may be absolutely necessary in higher security environments where integrity is required. This is especially true in regulated industries.
NAC is a complicated process that requires forethought. The first step is planning. A committee should convene and make decisions that define how NAC will work. Next, roles, identities, and permissions must be defined. Then these polices must be applied. As business needs change, NAC configuration must be reviewed to determine whether it should change, too.
That's it for this lesson. In this video, we discussed how Network Access Control is a concept that helps to ensure the integrity of a network system. It provides a more granular approach to providing network access by enforcing minimum requirements applied to devices.
You can define items such as anti-malware, OS versions, patch levels, and more. If devices don't meet these requirements, they're redirected to a remediation network. Once they're authenticated, devices are authorized and granted access. This is an ongoing process as business processes change and the organization grows.

5.6.2 Network Access Control Facts

This lesson covers the following topics:

- NAC overview
- Agent vs. agentless configurations
- NAC process

NAC Overview

Network access control (NAC) not only authenticates users and devices before allowing them access to the network but also checks and enforces compliance with established security policies. NAC ensures that devices meet a minimum set of security standards before being granted network access by evaluating:

- The operating system version
- Patch level
- Antivirus status
- The presence of specific security software

To ensure users and devices can only access the resources necessary to complete their duties, NAC can also restrict access based on:

- User profile
- Device type
- Location
- Other attributes

NAC plays a crucial role in identifying and quarantining suspicious or non-compliant devices. For organizations with bring-your-own-device (BYOD) policies and increasing use of IoT devices, NAC helps organizations secure their internal network environment against unauthorized access.

NAC and virtual local area networks (VLANs) work together to improve and automate network security. One of the primary ways NAC integrates with VLAN protections is through dynamic VLAN assignment. Dynamic VLAN assignment is a NAC feature that assigns a VLAN to a device based on the user's identity attributes, device type, device location, or health check results. For instance, a visiting user (such as a vendor) might be placed into a VLAN that only provides internet access, while a corporate user would be assigned to a VLAN with access to internal resources. Additionally, NAC can interact with dynamic VLAN to implement quarantine procedures. If a device is non-compliant with security policies—for example if it lacks updated antivirus software—the NAC system can automatically move it to a quarantine VLAN. This VLAN is generally isolated from the rest of the network, limiting potential damage from threats like malware.

NAC is often integrated with automatic remediation systems, which helps bring a computer into compliance when NAC discovers missing requirements. When such a system is used, a connecting device only has access to resources that can resolve or remediate the issues. After the issues have been remediated, the device is reevaluated and then allowed to access network resources, like the internet or databases.

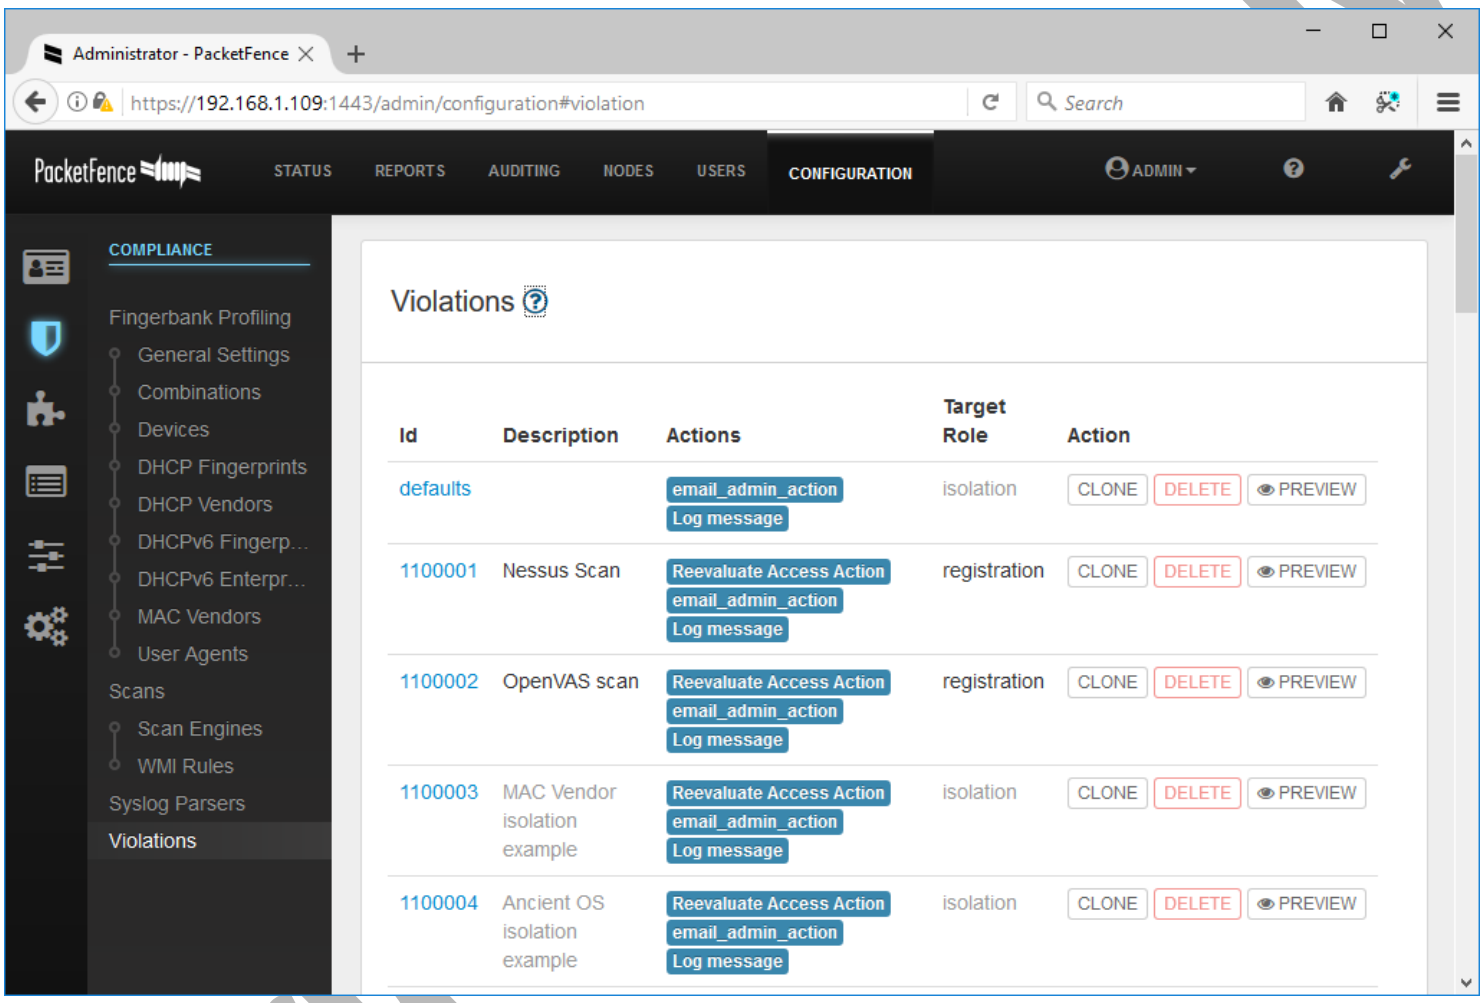
The NAC process is usually accomplished using a two-stage process of authentication and authorization. If the requirements for either of these stages are not met, the access request is denied. This is often referred to as zero-trust security, meaning nothing is trusted unless it can pass both the authentication and authorization stages.

- Authentication defines all the prerequisites a device must meet to access the network. This criteria is detailed for such things as anti-malware, OS, patch level, and so on.
- Authorization looks at the authentication information and applies the appropriate policies to provide the device with the access it’s defined to receive.

Agent vs. Agentless Configurations

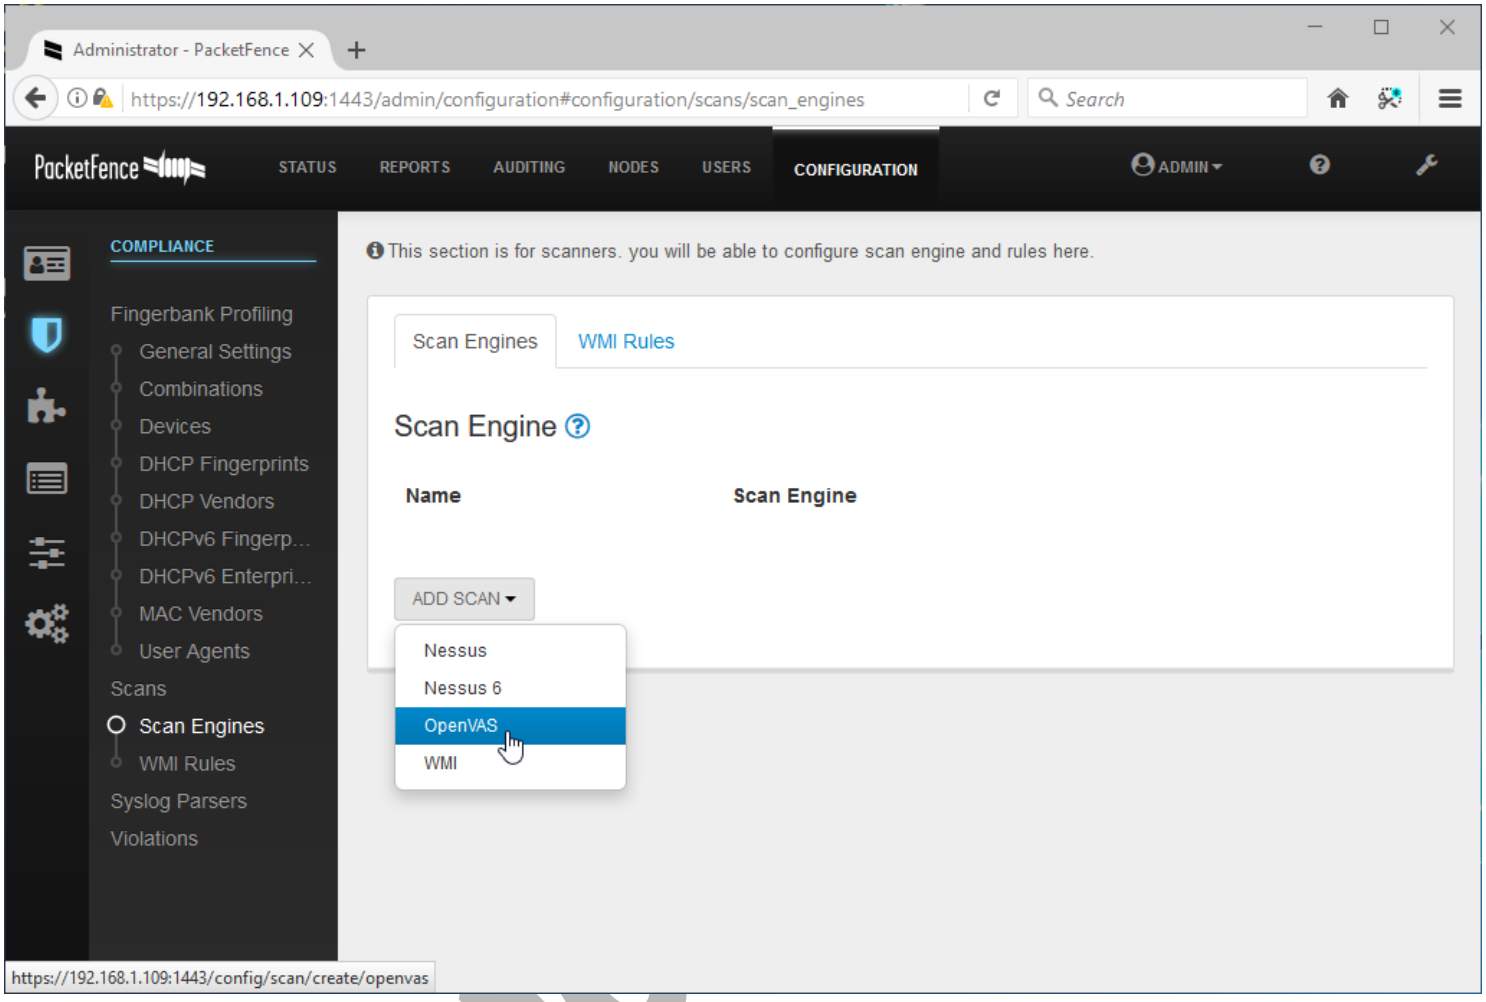
NAC can enforce security policies using agent-based and agentless methods. In an agent-based approach, a software agent is installed on the devices that connect to the network. This agent communicates with the NAC platform, providing detailed information about the device's status and compliance level. An agent-based NAC implementation can enable features such as automatic remediation, where the NAC agent can perform actions like updating software or disabling specific settings to bring a device into compliance with mandatory security configurations.

In contrast, an agentless NAC approach uses port-based network access control or network scans to evaluate devices. For example, agentless NAC may use DHCP fingerprinting to identify the type and configuration of a device when it connects, or it might perform a network scan to detect open ports or active services. While agentless methods may not provide as detailed information about a device's status, they can be used with any device that connects to the network, including guest or IoT devices, without requiring any prior configuration.



Defining policy violations in PacketFence Open Source NAC. (Screenshot used with permission from packetfence.org)

An agent can be persistent, in which case it is installed as a software application on the client or nonpersistent. A nonpersistent (or dissolvable) agent is loaded into memory during posture assessment but is not installed on the device.



PacketFence supports the use of several scanning techniques, including vulnerability scanners, such as Nessus and OpenVAS, Windows Management Instrumentation (WMI) queries, and log parsers. (Screenshot used with permission from packetfence.org)

NAC Process

NAC is a complicated process that requires forethought. Use the following process when implementing NAC:

- Plan - A committee should convene and make decisions that define how NAC should work.
- Define - The roles, identities, and permissions (policies) must be defined.
- Apply - Once defined, the policies must be applied.
- Review/Revise - As business needs change, the process must be reviewed to determine whether changes are required.

5.6.3 Practice Questions (Section Quiz)

q_nac_agentless_secp8

Which of the following NAC agent types would be used for IoT devices?

Answers:

- Dissolvable
- ***Agentless**
- Zero-trust
- Permanent

Explanation:

An agentless agent is on the domain controller. When the user logs into the domain, it authenticates with the network. Agentless NAC is often used when there is limited disk space, such as for Internet of Things (IoT) devices.

A dissolvable agent is downloaded, or a temporary connection is established. The agent is removed once the user is done with it.

Zero-trust security means nothing is trusted unless it can pass both the authentication and authorization stages.

A permanent agent resides on a device permanently.

q_nac_apply_secp8

Which of the steps in the Network Access Control (NAC) implementation process occurs once the policies have been defined?

Answers:

- Plan
- ***Apply**
- Review
- Test

Explanation:

The third step in implementing NAC is to apply the policies. This occurs after the policies have been defined.

Planning is the first step in the NAC implementation process and needs to be done before defining the policies.

Review is the final step in the NAC implementation process. As business needs change, the process must be reviewed to determine whether changes are required.

Testing is not a step in the NAC implementation process.

q_nac_authentication_secp8

Which of the following defines all the prerequisites a device must meet in order to access a network?

Answers:

- Authorization
- ***Authentication**
- Zero-trust security
- Identity Services Engine (ISE)

Explanation:

Authentication defines all the prerequisites a device must meet in order to access a network. These criteria are detailed for such things as anti-malware, OS, and patch level.

Authorization looks at the authentication information and applies the appropriate policies to provide the device with the access it's defined to receive.

Zero-trust security means nothing is trusted unless it can pass both the authentication and authorization stages.

Identity Services Engine (ISE) is Cisco's NAC solution.

q_nac_authorization_secp8

Which of the following applies the appropriate policies in order to provide a device with the access it's defined to receive?

Answers:

- ***Authorization**
- Authentication
- Zero-trust security
- Identity Services Engine

Explanation:

Authorization looks at the authentication information and applies the appropriate policies in order to provide a device with the access it's defined to receive.

Authentication defines all the prerequisites a device must meet in order to access a network. These criteria are detailed for such things as anti-malware, OS, patch level, and so on.

Zero-trust security means nothing is trusted unless it can pass both the authentication and authorization stages.

Identity Services Engine (ISE) is Cisco's NAC solution.

q_nac_automatic_remediation_secp8

As a network administrator, you have implemented a Network Access Control (NAC) system with automatic remediation capabilities in your organization.

One day, you notice that a significant number of devices are being quarantined frequently by the NAC system due to non-compliance with security policies.

What should be your next course of action?

Answers:

- Ignore the issue as the NAC system is doing its job by quarantining non-compliant devices.
- Disable the automatic remediation feature to reduce the number of quarantined devices.
- ***Investigate the root cause of the frequent non-compliance and address it.**
- Reduce the security standards set by the NAC system to decrease the number of quarantined devices.

Explanation:

Investigating the root cause of the frequent non-compliance is the best course of action. It could be due to outdated software on the devices, overly strict security policies, or other factors. Once the root cause is identified, it can be addressed, which should reduce the number of quarantined devices and improve the overall security of the network.

Ignoring the issue is not a good practice. Frequent quarantining of devices indicates a potential problem with the devices' security compliance or with the NAC system's policies. It's important to investigate and address the issue to ensure the security and functionality of the network.

Disabling the automatic remediation feature may reduce the number of quarantined devices, but it also reduces the effectiveness of the NAC system. The automatic remediation feature is designed to help bring non-compliant devices into compliance, not to be disabled when it's inconvenient.

Reducing the security standards set by the NAC system may decrease the number of quarantined devices, but it also weakens the security of the network. The standards are there to protect the network and should not be reduced without a good reason.

q_nac_nonpersistent_agent_secp8

In a Network Access Control (NAC) system, a nonpersistent (or dissolvable) agent is used during the posture assessment process.

Which of the following statements about a nonpersistent NAC agent is true?

Answers:

- A nonpersistent agent remains on the device indefinitely after the posture assessment.
- A nonpersistent agent requires prior configuration on the device before it can be used.
- A nonpersistent agent cannot provide detailed information about a device's status and compliance level.
- ***A nonpersistent agent is loaded into memory during posture assessment but is not installed on the device.**

Explanation:

A nonpersistent agent is loaded into memory during the posture assessment process but is not permanently installed on the device. It is removed from memory after the assessment is completed.

A nonpersistent agent does not remain on the device after the posture assessment. It is removed from memory after the assessment is completed, which is why it is also referred to as a "dissolvable" agent.

A nonpersistent agent can be used with any device that connects to the network, including guest or IoT devices. It does not require any prior configuration on the device, making it a flexible option for assessing a variety of devices.

Even though a nonpersistent agent is not permanently installed on the device, it can still provide detailed information about the device's status and compliance level during the posture assessment process.

q_nac_plan_secp8

You are part of a committee that is meeting to define how Network Access Control (NAC) should be implemented in the organization.

Which step in the NAC process is this?

Answers:

- ***Plan**
- Apply
- Review
- Define

Explanation:

Planning is the first step in the NAC implementation process. In this step, a committee should convene and make decisions that define how NAC should work.

The third step in implementing NAC is to apply the policies. This occurs after the policies have been defined.

Review is the final step in the NAC implementation process. As business needs change, the process must be reviewed to determine whether changes are required.

Define is the second step in the NAC implementation process. After the committee has decided how NAC should work, the roles, identities, and permissions (policies) must be defined.

q_nac_vlan_01_secp8

A large enterprise recently introduced a bring your own device (BYOD) policy and is seeing an uptick in the use of Internet of Things (IoT) devices in the office.

Concerns about unauthorized network access and compliance with security standards accompany these changes.

Assess the following options and determine the MOST suitable strategy to alleviate these security concerns.

Answers:

- ***Deploy agent-based Network Access Control (NAC) with dynamic Virtual Local Area Networks (VLANs) and firewall integration.**
- Depend solely on the existing firewall for device authentication.
- Implement agentless Network Access Control (NAC) without firewall integration.
- Use Network Access Control (NAC) without employing dynamic Virtual Local Area Networks (VLANs).

Explanation:

An agent-based NAC approach combined with dynamic VLAN assignment and firewall integration provides a comprehensive solution. The solution offers robust device authentication, security policy compliance, and flexibility to accommodate various device types and user roles.

While essential for network security, firewalls do not offer the granular control and compliance enforcement that an agent-based NAC can provide.

While agentless NAC can accommodate a variety of devices without prior configuration, its information about a device's status and compliance is less detailed than that of agent-based NAC.

Employing NAC without using dynamic VLANs limits the system's ability to effectively manage network access based on user identity attributes, device type, or compliance status.

q_nac_vlan_02_secp8

An international business is experiencing an increase in remote work scenarios, resulting in a significant rise in employees using personal devices and smart appliances for work.

This development raises potential issues related to unauthorized network access and adherence to security standards.

Which of the following solutions MOST effectively addresses these security issues?

Answers:

- ***Deploy agent-based Network Access Control (NAC) with dynamic Virtual Local Area Networks (VLANs) and firewall integration.**
- Depend solely on the existing firewall for device authentication.
- Implement agentless Network Access Control without firewall integration.
- Use Network Access Control (NAC) without employing dynamic Virtual Local Area Networks (VLANs).

Explanation:

An agent-based NAC approach combined with dynamic VLAN assignment and firewall integration provides a comprehensive solution. The solution offers robust device authentication, security policy compliance, and flexibility to accommodate various device types and user roles.

While essential for network security, firewalls do not offer the granular control and compliance enforcement that an agent-based NAC can provide.

While agentless NAC can accommodate a variety of devices without prior configuration, its information about a device's status and compliance is less detailed than that of agent-based NAC.

Employing NAC without using dynamic VLANs limits the system's ability to effectively manage network access based on user identity attributes, device type, or compliance status.

q_nac_zero_trust_secp8

Which of the following BEST describes zero-trust security?

Answers:

- All devices are trusted.
- Only devices that pass authentication are trusted.
- Only devices that pass authorization are trusted.
- ***Only devices that pass both authentication and authorization are trusted.**

Explanation:

Network Access Control (NAC) is usually accomplished using a two-stage process of authentication and authorization. If the requirements for either of these stages is not met, the access request is denied. This is often referred to as zero-trust security, meaning nothing is trusted unless it can pass both the authentication and authorization stages.

Zero-trust is designed to verify trust and access of devices, filtering out those that do not authenticate properly. That being the case, not all devices are trusted when you use zero-trust security.

Zero-trust requires that devices pass both authentication and authorization--not one or the other.

5.7 Network Device Vulnerabilities

As you study this section, answer the following questions:

- For security, what is the first thing you should do when new hardware and software is turned on for the first time?
- What are the characteristics of a complex password?
- Why is it important to apply new firmware or patches for devices?
- What are major risks of hard-coded passwords on devices throughout the enterprise?
- What are the resources you can use to keep track of existing technology vulnerabilities in an organization?

In this section, you will learn to:

- Search for default passwords.
- Establish an unauthorized SSH connection.
- Secure a switch.

The key terms for this section include:

Term	Definition
Privilege escalation	A software bug or design flaw in an application that allows an attacker to gain access to system resources or additional privileges that aren't typically available.
Backdoor	An unprotected and usually lesser known access method or pathway that may allow attackers access to system resources.
Zero-day vulnerability	A software vulnerability that is unknown to the vendor that can be exploited by attackers.
Common Vulnerabilities and Exposures (CVEs)	A repository of vulnerabilities hosted by MITRE Corporation.

This section helps you prepare for the following certification exam objectives:

Exam	Objective
CompTIA Security+ SY0-701	2.3 Explain various types of vulnerabilities. • Misconfiguration • Zero-day

	2.4 Given a scenario, analyze indicators of malicious activity. • Privilege escalation 4.6 Given a scenario, implement and maintain identity and access management. • Password concepts o Password best practices ▪ Length ▪ Complexity
TestOut Security Pro	2.2 Harden Network Devices 2.2.1 Configure and Access a Switch

5.7.1 Device Vulnerabilities (Lesson Video)

Transcript:

Attackers try to exploit a wide range of potential vulnerabilities that organizations may not realize they even have. For this reason, security professionals must do all they can to reduce the attack surface their company presents. In this lesson, I'll discuss several methods for reducing your attack surface and creating a company profile that's as secure as possible. Let's first look as some often-misconfigured devices that may open up opportunities for an attack.

Remember that your attack surface increases each time a device is added to your network. This provides threat actors more opportunities to find openings in your network shield. These malicious users continually look for entry points, so it's important to ensure that each new device is properly configured and protected.
For example, firewalls are one of those entry points that are often misconfigured. Knowing this, attackers often look for firewalls with too many open ports or other security weaknesses. In addition, servers or appliances that are set up to block malicious payloads in emails could let spam and malware into the company if not configured properly. This could lead to data loss or corruption. Wireless access points are another area that, if not configured appropriately, could lead to potential attacks by allowing attackers into the production network. Using weak or outdated security protocols such as WEP is an open invitation for attackers. Once they have access to the internal network, the damage quotient is critically high.
Another attack surface to be aware of is security. The old adage says, "A chain is only as strong as its weakest link." Attackers are experts at finding the smallest hole or chink in the armor. If they want in, they'll get in. The question is how difficult it'll be for them.
Unfortunately, when something works, it's often difficult to make changes. For compatibility reasons, administrators might use outdated and insecure security protocols such as SHA1 and WEP. So every effort to utilize updated and secure protocols such as 3DES, SHA-256, and AES should be made. Another easy security attack comes from using the default credentials for your network devices, such as routers. Most attackers find that a 10 second Google query can provide the default username and password for commonplace devices. With little effort, an attacker can usually discover the make and model of the device he or she wants to attack. Those are the credentials they'll try first. To help overcome this weakness, some manufacturers are becoming more security conscious and require a change to the defaults as part of the installation process. Others make their device inoperable until the default configuration credentials are changed.
As computer networking professionals, we're very familiar with operating system and application software updates. These updates provide the latest patches, add functionality, and close security holes. The same is true for firmware. Firmware updates might include protocol updates that enable newer, more secure encryption. As an example, the famous WannaCry ransomware attack of 2017 took
advantage of a weakness inherent in the SMBv1 Protocol that allowed a remote attacker to take complete control of the affected system. This could've been prevented with security-minded updates.

Now, let's look at credential management. Unfortunately, some administrators use the same credentials in an attempt to ease the device management burden. Even though the new credentials might be different from the default ones, doing this is still a massive security risk. It might be convenient, but if any one device becomes comprised, the attacker then has access to all device configurations. Your network is greatly compromised when this happens, and you might even have to reset all your devices to factory defaults and reconfigure them.

Another potential vulnerability concern is the use of discretionary credentials. The principle of least privilege is paramount here. Users should only be given credentials with permissions that match their specific job responsibilities. If a user is given more privileges than he or she needs, an attacker could use their account to find much more potentially sensitive data than would otherwise be the case.

Next, let's go over physical access. If someone is given physical access to a device, there's very little opportunity for protection. For example, an attacker can change passwords or add credentials to a firewall with physical access. Or they can use a USB flash drive to copy data or inject malware. As such, you should confine infrastructure equipment to secure areas that only authorized personnel have access to. In addition, you should make sure that any attempted access without proper credentials sets off alarms and alerts.

One of the hard things about keeping your devices safe is trying to protect them from unknown vulnerabilities. Unknown vulnerabilities are often referred to as zero-day vulnerabilities. A zero-day vulnerability is a software security weakness that's unknown to the developer. Since these vulnerabilities are unknown, attackers who discover them quietly try to continue exploiting them without detection. Once brought to the developers' attention, they'll obviously want to fix them as quickly as possible. The best way to protect yourself from zero-day vulnerabilities is to keep your software updated. When a zero-day vulnerability is announced, patch it as quickly as possible.

Keeping up with the vastness of known vulnerabilities is also a monumental task. Fortunately, there's some help available for network administrators.

The National Institute of Standards and Technology, or NIST, has a publication that serves as a national database of known vulnerabilities. In addition, they provide vulnerability metrics called the Common Vulnerability Scoring System, or CVSS. The NIST website states that CVSS is an open framework for communicating the characteristics and severity of software vulnerabilities. After evaluating known vulnerabilities, CVSS produces a score from zero to ten, letting you calculate the vulnerability's severity. This score helps you determine the best course of action to take.

Another method of knowing about vulnerabilities is to use the Common Vulnerabilities and Exposures system, or CVE system. The system's goal is to make it easier to share information about known vulnerabilities across organizations. This is done by creating unique, standardized CVE identifiers to let you access information about specific cyber threats across multiple information sources. You can download CVE lists in several different formats. As of the writing of this lesson, there are well over 175,000 identified vulnerabilities.

That's it for this lesson. In this lesson, we discussed the need for enterprises to protect their infrastructure. Some best practices to ensure protection are to not use outdated firmware, default configurations, or weak security settings. Additionally, systems administrators need to make sure that software patches are applied in a timely manner and that bad credential management practices, like discretionary credentials, are avoided. Since securing physical access points is critical to an organization's survival, you must have an airtight infrastructure in place to do this. Finally, we talked about a few resources available to help you catalog and identify common vulnerabilities and exposures.

5.7.2 Device Vulnerability Facts

This lesson covers network device vulnerabilities.

Network Device Vulnerabilities

A knowledgeable attacker can exploit network device vulnerabilities to gain access to network resources. Network device vulnerabilities include:

Vulnerability	Description

Default accounts and passwords	Default accounts and passwords are factory defaults that already exist when a new network device is configured at installation. Default account names and passwords should be changed immediately when hardware or software is turned on for the first time.
Weak passwords	Weak passwords are passwords that are blank, too short, dictionary words, or simple. In other words, they are passwords that can be quickly identified using password-cracking tools. Password cracking is the process of recovering secret passwords from data stored in or transmitted by a computer system. Enforce complex passwords to reduce the risks of weak passwords. Complex passwords require passwords of a certain length (typically over eight characters) and a mix of character types (numbers and symbols), along with requirements that the passwords are not words, variations of words, or derivatives of the username.
Privilege escalation	Privilege escalation allows a user to take advantage of a software bug or design flaw in an application to gain access to system resources or additional privileges that are not typically available to that user. Examples of privilege escalation include: • A user accessing a system with a regular user account that is able to access functions reserved for higher-level user accounts (such as administrative features). • A user who is able to access content that should only be accessible to a different user. • A user who should only have administrative access that can access content that should only be available to a regular user. Privilege escalation does not occur when a user is able to steal or hack administrator credentials and is, therefore, able to access administrative functions. Privilege escalation refers to accessing features with an account that normally should not have access to those features.
Backdoors	A backdoor is an unprotected access method or pathway. Backdoors: • Include hard-coded passwords and hidden service accounts. • Are often added during development as a shortcut to circumvent security. If they are not removed, they present a security problem. • Can be added by attackers who have gained unauthorized access to a device. When added, the backdoor can be used at a future time to bypass security controls easily. • Can be used to control the device remotely at a later date. • Rely on secrecy to maintain security. To protect against backdoors, do not allow programmers to bypass security during development. Carefully examine the code before release to remove any traces of backdoors that might have been included.
Zero-day	Zero-day vulnerabilities refer to previously unknown software or hardware flaws that attackers can exploit before developers or vendors become aware of or have a chance to fix them. The term zero-day signifies that developers have "zero days" to fix the problem once the vulnerability becomes known. These vulnerabilities are significant because they can cause widespread damage before a patch is available.

	An attacker exploiting a zero-day vulnerability can compromise systems, steal sensitive data, launch further attacks, or cause other forms of harm, often undetected. The stealth and unpredictability of zero-day attacks make them particularly dangerous. They are a favored tool of advanced threat actors, such as organized crime groups and nation-state attackers, who often use them in targeted attacks against high-value targets, such as governmental institutions and major corporations. Since these vulnerabilities are unknown to the public or the vendor during exploitation, traditional security measures like antivirus software and firewalls, which rely on known signatures or attack patterns, are often ineffective against them. The discovery of a zero-day vulnerability typically triggers a race between threat actors, who aim to exploit it, and developers, who work to patch it. Upon discovering a zero-day vulnerability, ethical security researchers usually follow a process known as responsible disclosure, designed to privately inform the vendor so a patch can be developed before the vulnerability is publicly disclosed. This practice aims to limit the potential harm caused by discovering a zero-day vulnerability. The term zero-day is usually applied to the vulnerability itself but can also refer to an attack or malware that exploits it. Zero-day vulnerabilities have significant financial value. A zero-day exploit for a mobile OS can be worth millions of dollars. Consequently, an adversary will only use a zero-day vulnerability for high-value attacks. State security and law enforcement agencies are known to stockpile zero-days to facilitate the investigation of crimes.

5.7.3 Searching for Default Passwords (Demo Video)

Transcript:

In this demonstration, we'll look at some default network device passwords. When you install a new network device, it's almost always going to have some sort of default administrative account with an associated password. You can find these by doing a search for default network device passwords, like I did up here.

Some states and countries require unique passwords for each device. Here's the website for the State of California Legislature. If I scroll down, you can see where I highlighted this line, "The preprogrammed password is unique to each device manufactured." That means in order to sell devices in this state, I have to make sure each one has a unique password. Since these sort of laws have been implemented, most manufactures are doing this for devices sold anywhere, which is a good practice. But not all devices come with unique passwords, especially enterprise equipment. On legacy equipment, having default passwords presents a security issue because these usernames and passwords are very well known and very easy to find. If someone learns your device's make and model and you haven't changed the default password, they could cause some serious damage.
Let's say we have a Netgear router, and we want to find out what the default password is. Well, I did a search, like we already saw, and here are some of the sites I found.
This first one, CIRT.net, is a pretty good site. It has over 2,100 default passwords on it. And if we come down here, we can find Netgear, and you can see a variety of different makes and models. It looks like for admin, password is a common default password for Netgear.
Let's check out another one, datarecovery.com. I'll press Ctrl+F to do a search and type in â€˜netgear'. I'll move down, and we can see a list of Netgear devices. Once again, you can see the usernames and passwords. This one's credentials are admin and password.
Let's look at one more site. This one is routerpasswords.com. I can come down and look for our Netgear devices again. I'll click on Find Passwords and see the variety of different Netgear network devices they've listed. On this site, it looks like most of the default usernames and passwords are admin and password, although there is some variance. We can also see how you interface with the device, whether it's over a web browser using HTTP, FTP, or some other way.
That's it for this demo. We searched the web for some default usernames and passwords for network devices. Remember, always change the default username and password on new network devices. Leaving default credentials presents a huge security risk.

5.7.4 Unauthorized SSH Connection (Demo Video)

Transcript:

Malicious users sometimes gain access to systems with SSH connections. It's not a good idea to allow root access through SSH, but many admins modify their systems to allow it anyway. Once a malicious user has access to the system, they can pretty much do what they want. In this demo, we're going to gain access to a Linux system and create an unauthorized SSH session.

The first thing we need to do is find our target. I'm on a Kali Linux system with a terminal open. I'm going to do a ping sweep using nmap on my subnet. I already know that my subnet is 10.10.10.0. So, to do this, I'll type '10.10.10.0/24', or I could also put in the IP range. In this case, that would be '10.10.10.1-254'. Press Enter.
My scan completes, and down here, I can see that it found four hosts. Up here, I can see that I have a device called Router with the IP of 10.10.10.1, so that's going to be my target. I'll clear the screen. And now, I want to scan just that IP to see which ports are open. The scan completes, and this, right here, is what I'm interested in. I see that SSH is running on port 22 on this system.
Now, let's use nmap and run a script that will attempt to brute force the username and password. nmap comes with something called the Nmap scripting engine. One of those scripts is for brute forcing SSH. So, let's type that in, 'nmap --script=ssh-brute 10.10.10.1', and press Enter. nmap will begin the process of attempting to brute force the username and password. nmap is using a built-in default username list and a password list to do this. First, it will grab a username and try a password. Then it goes to the next username and tries the next password. I'm on a virtual machine without a lot of system resources, so this is going to take some time. So, while this is running, I'll pause the recording.
All right. The scan finished up, and we can see, here, that it found the username Root and the password, which is a variation of the word "password." The brute force made 2,270 guesses, and it took just a little over 600 seconds to complete the process. As I mentioned, this is a virtual machine, so the scanning goes a lot slower. But I do happen to know that the password it found is near the top of the list of tens of thousands of passwords. So, depending on your system and your password file, your results could be substantially different.
Now that we know our username and password, let's try to make an unauthorized SSH connection to that system. I'm going to jump over to a Windows 10 system and try the connection from there.
All right. I'm on this Windows 10 machine, and up here, I have a program called PuTTY. PuTTY is a free and open-source terminal emulator, serial console, and network file transfer application. It supports several network protocols, including SCP, SSH, Telnet, rlogin, and other connections. It's often used to connect to switching and routing equipment. To make a connection, I'll type in the IP address for our victim machine, '10.10.10.1'. Under Port, 22 is already entered, so I'll just hit Enter.
Now, a terminal opens up. It's asking for a login name, so I'll put in 'root'. And now it wants my password, so I'll type in the variation of the word "password" that we saw earlier. Press Enter, and I'm logged in! So, whatever's possible to do in a terminal, I'm able to do--that gives me a lot of options.
Okay. I still want to look at one more thing, and that's to log in to that victim machine to see what's going on while this SSH session is running.
Let's go over to this Linux system. This is actually a Linux distribution that's used as a firewall and router. I'm going to go ahead and log in to the GUI. Once I've logged in, I'm not really able to tell that there's an SSH session going on at the exact same time.
That's it for this demo. In this demo, we performed an unauthorized SSH connection. First, we scanned our subnet with nmap to find our victim. Then we used an nmap script to brute force the username and password. We used that information to make the SSH connection to the victim machine using the program PuTTY. And we wrapped up by logging in to the victim machine's GUI to verify that the SSH session wan't detected.

5.7.5 Securing a Switch (Demo Video)

Transcript:

In this demonstration, we're going to secure access to our network switch. We're using a Cisco Small Business Switch, which has a web interface for access and configuration.

We access the switch by typing its IP address, 192.168.254.8, into a web browser. And here's the login page.
This is a new switch, so it still has the default user name and password configured of cisco and cisco, which we'll enter and then click Log In.
Now, the default user name and password for this device can be found very easily, so you can tell that this switch is not very secure right now.
Normally, the first thing you should do with a new network device is change the default user name and password.
On this device, we can use the Change Device Password link under Quick Access to do this.
This takes us directly to the User Accounts page under Administration. And here's the default user, cisco. Let's first create another user. Click Add. Enter ciscoAdmin for the user name.
Enter a strong, complex password. And we want Read/Write Management Access. And click Apply. And we can see the new ciscoAdmin user here.
We also want to change the password for the default user.
So we'll select the cisco user and click Edit. And again we want to use a complex password. And for this user, let's also change the user level. We'll select Read-Only CLI Access.
This way, if someone is able to get into the switch using the default account, they won't be able to change anything. And we'll click Apply.
So, the first thing we've done to secure access to our switch is add another admin account with a custom user name and a complex password. We then changed the default user's password and set the user level to read-only.
Doing this makes it harder for people to get into our switch here and change the configuration. And this should be the first step you do with any new network device.
Now, there's one more important step to take here. And that's to save the changes we've to the startup config. If we don't, as soon as the switch is rebooted, the changes will be lost; we don't want this.
So we'll click Save to go to the Copy/Save Configuration page. And here we want to save the contents of the Running configuration to the Startup configuration. And click Apply. Now when the device reboots, it will load our custom configuration.
That's it for this demonstration. In this demo, we secured access to our network switch. First we added a new management user with full access. We changed the default user's password. And then we saved our changes to the startup configuration file.

5.7.6 Secure a Switch (Simulation)

Scenario

You are the IT security administrator for a small corporate network. You need to secure access to your switch, which is still configured with the default settings.

Access the switch management console through Chrome on **http://192.168.0.2** with the username **cisco** and password **cisco**.

In this lab, your task is to:

- Create a new user account with the following settings:
  - Username: **ITSwitchAdmin**
  - Password: **Admin$only1844**
  - User Level: **Read/Write Management Access (15)**
- Edit the default user account as follows:
  - Username: **cisco**
  - Password: **CLI$only1958**
  - User Level: **Read-Only CLI Access (1)**
- Save the changes to the switch's startup configuration file.

Explanation

Complete this lab as follows:

1. Log in to the CISCO switch.
    a. From the taskbar, select **Google Chrome** .
    b. In the URL field, enter **192.168.0.2** and press **Enter** .
    c. Maximize the window for better viewing.
    d. In the Username and Password fields, enter **cisco** (case sensitive).
    e. Select **Log In** .
2. Create a new user account.
    a. From Getting Started under Quick Access, select **Change Device Password** .
    b. Select **Add** .
    c. For the username, enter **ITSwitchAdmin** (case sensitive).
    d. For the password, enter **Admin$only1844** (case sensitive).
    e. For Confirm Password, enter **Admin$only1844** .
    f. For the User Level, make sure **Read/Write Management Access (15)** is selected.
    g. Select **Apply** .
    h. Select **Close** .
3. Edit the default user account.
    a. Under User Account Table, select **cisco** (the default user) and then select **Edit** .
    b. For the password, enter **CLI$only1958** .
    c. For Confirm Password, enter **CLI$only1958** .
    d. For User Level, select **Read-Only CLI Access (1)** .
    e. Select **Apply** .
4. Save the changes to the switch's startup configuration file.
    a. From the top of the switch window, select **Save** .
    b. On the left, select **Copy/Save Configuration** .
    c. On the right, under *Source File Name* , make sure **Running configuration** is selected.
    d. Under *Destination File Name* , make sure **Startup configuration** is selected.
    e. Select **Apply** .
    f. Select **OK** .
    g. Select **Done** .

5.7.7 Practice Questions (Section Quiz)

q_dev_vuln_backdoor_01_secp8

While developing a network application, a programmer adds functionally that allows her to access the running program without authentication so she can capture debugging data. The programmer forgets to remove this functionality prior to finalizing the code and shipping the application.

Which type of security weakness does this describe?

Answers:

- ***Backdoor**
- Privilege escalation
- Weak password
- Buffer overflow

Explanation:

A backdoor is an unprotected access method or pathway. Backdoors may include hard-coded passwords or hidden service accounts. They are often added during development as a shortcut to circumvent security. If they are not removed, they present a security problem.

Privilege escalation allows a user to take advantage of a software bug or design flaw in an application to gain access to system resources or additional privileges that would typically not be available to the user.

Weak passwords are passwords that are blank, too short, dictionary words, or not complex enough. This allows them to be quickly identified using password-cracking tools.

A buffer overflow occurs when the operating system or an application does not properly enforce boundaries for how much and which type of data can be inputted.

q_dev_vuln_backdoor_02_secp8

An attacker was able to gain unauthorized access to a mobile phone and install a Trojan horse so that he or she could bypass security controls and reconnect later.

Which type of attack is this an example of?

Answers:

- Social engineering
- Replay
- ***Backdoor**
- Privilege escalation

Explanation:

A backdoor is an unprotected access method or pathway. Backdoors:

- Include hard-coded passwords and hidden service accounts.
- Are often added during development as a shortcut to circumvent security. If they are not removed, they present a security problem.
- Can be added by attackers who have gained unauthorized access to a device. When added, the backdoor can be used at a future time to easily bypass security controls.
- Can be used to remotely control the device at a later date.
- Rely on secrecy to maintain security.

Social engineering attacks involve stealing information or convincing someone to perform an inappropriate activity via email, via phone, or in person.

A replay attack is a network attack that occurs when an attacker intercepts data and fraudulently delays or re-transmits it.

Privilege escalation allows a user to take advantage of a software bug or design flaw in an application to gain access to system resources or additional privileges that aren't typically available to that user.

q_dev_vuln_backdoor_03_secp8

In an effort to increase the security of your organization, programmers have been informed they can no longer bypass security during development.

Which vulnerability are you attempting to prevent?

Answers:

- Social engineering
- Replay
- ***Backdoor**
- Privilege escalation

Explanation:

A backdoor is an unprotected access method or pathway. Backdoors:

- Include hard-coded passwords and hidden service accounts.
- Are often added during development as a shortcut to circumvent security. If they are not removed, they present a security problem.
- Can be added by attackers who have gained unauthorized access to a device. When added, the backdoor can be used at a future time to easily bypass security controls.
- Can be used to remotely control the device at a later date.
- Rely on secrecy to maintain security.

Social engineering attacks involve stealing information or convincing someone to perform an inappropriate activity via email, phone, or in person.

A replay attack is a network attack that occurs when an attacker intercepts data and fraudulently delays or re-transmits it.

Privilege escalation allows a user to take advantage of a software bug or design flaw in an application to gain access to system resources or additional privileges that aren't typically available to that user.

q_dev_vuln_complex_secp8

Which of the following are characteristics of a complex password? (Select two.)

Answers:

- Has a minimum of six characters
- ***Has a minimum of eight characters**
- Consists of letters and numbers only
- ***Consists of letters, numbers, and symbols**
- Has a maximum of fifteen characters

Explanation:

Complex passwords require a certain length (typically over eight characters) and a mix of character types (numbers and symbols) along with requirements that the password not consist of words, variations of words, or derivatives of the username.

There is no maximum character limit for a complex password.

q_dev_vuln_cracking_secp8

An attacker has gained access to the administrator's login credentials.

Which type of attack has MOST likely occurred?

Answers:

- Privilege escalation
- Backdoor
- ***Password cracking**
- Buffer overflow

Explanation:

Password cracking is the process of recovering secret passwords from data that has been stored in or transmitted by a computer system. If an attacker has gained access to the administrator's login credentials, this is most likely the cause of a password-cracking attack.

Privilege escalation allows a user to take advantage of a software bug or design flaw in an application to gain access to system resources or additional privileges that would typically not be available to the user.

A backdoor is an unprotected access method or pathway. Backdoors may include hard-coded passwords or hidden service accounts.

A buffer overflow attack occurs when the operating system or an application does not properly enforce boundaries for how much and which type of data can be inputted.

q_dev_vuln_privilege_01_secp8

A relatively new employee in the data entry cubical farm was assigned a user account similar to the other data entry employees' accounts. However, audit logs have shown that this user account has been used to change ACLs on several confidential files and has accessed data in restricted areas.

This situation indicates which of the following has occurred?

Answers:

- Physical security
- Social engineering
- External attack
- ***Privilege escalation**

Explanation:

This situation describes the result of a successful privilege escalation attack. If a low-end user account is detected performing high-level activities, it is obvious that the user account has somehow gained additional privileges.

Physical security is the protection of corporate assets from threats such as theft or damage.

Social engineering attacks involve stealing information or convincing someone to perform an inappropriate activity via email, phone, or in person.

External attacks are when unauthorized individuals try to breach a network from off-site.

q_dev_vuln_privilege_02_secp8

An attacker has obtained the logon credentials for a regular user on your network.

Which type of security threat exists if this user account is used to perform administrative functions?

Answers:

- ***Privilege escalation**
- Social engineering
- Replay
- Impersonation

Explanation:

Privilege escalation allows a user to take advantage of a software bug or design flaw in an application to gain access to system resources or additional privileges that are typically not available to normal users. Examples of privilege escalation include:

- A user accessing a system with a regular user account and successfully accessing functions reserved for higher-level user accounts (such as administrative features).
- A user who is able to access content that should be accessible only to a different user.
- A user who should have only administrative access being able to access content that should only be accessible to a regular user.

Privilege escalation does not occur when a user is able to steal or hack administrator credentials and is, therefore, able to access administrative functions. Privilege escalation refers to accessing features with an account that normally should not have access to those features.

q_dev_vuln_privilege_03_secp8

Travis and Craig are both standard users on the network. Each user has a folder on the network server that only they can access. Recently, Travis has been able to access Craig's folder.

This situation indicates which of the following has occurred?

Answers:

- Social engineering
- Replay
- External attack
- ***Privilege escalation**

Explanation:

This situation describes the result of a successful privilege escalation attack. If a user is able to access content that should only be accessible to a different user, it is obvious that a privilege escalation attack has occurred.

Social engineering attacks involve stealing information or convincing someone to perform an inappropriate activity via email, phone, or in person.

A replay attack is a network attack that occurs when an attacker intercepts data and fraudulently delays or re-transmits it.

External attacks are when unauthorized individuals try to breach a network from off-site.

q_dev_vuln_zero-day_01_secp8

In a rapidly evolving IT environment, a cloud service provider offers various services to businesses, enabling them to store and process data securely. To enhance security, the provider regularly updates its systems and software.

Despite these efforts, a security researcher discovers a previously unknown vulnerability in one of the cloud-specific applications, leaving customer data exposed to potential threats.

In this scenario, which vulnerability is the security researcher likely to have found in the cloud-specific application?

Answers:

- ***Zero-day vulnerability**
- Network misconfiguration
- SQL injection vulnerability
- Cross-site scripting (XSS) vulnerability

Explanation:

A zero-day vulnerability refers to a security flaw previously unknown to the vendor or developer. The discovery of this previously unknown vulnerability aligns with the characteristics of a zero-day vulnerability.

In the scenario provided, the focus is on a vulnerability identified within a cloud-specific application that is distinct from a misconfiguration in the network settings and often involves errors in firewall rules, access controls, or other network-related configurations.

SQL injection is a prevalent type of cyberattack where malicious actors exploit vulnerabilities in web applications to insert malicious SQL queries into the application's database.

Malicious script injection, also known as cross-site scripting (XSS), is when attackers inject malicious scripts into web pages to compromise users' sessions or steal sensitive information.

q_dev_vuln_zero-day_02_secp8

In the context of information security, an organization discovers a zero-day vulnerability in its database software.

At the same time, a known hacking group has expressed intentions to target entities using this specific software.

Which of the following BEST describes this situation's relation to vulnerability, threat, and risk?

Answers:

- The organization conducts regular vulnerability assessments to maintain its security posture.
- The organization mitigates the risk by improving physical security and firewall configurations.
- The organization hires an external cybersecurity firm to identify potential threats.
- ***The organization increases its risk of a security breach due to the threat and vulnerability.**

Explanation:

This option illustrates a scenario in which an external group (threat) threatens a vulnerability (the software weakness), raising the possibility of a security breach (risk).

While conducting regular vulnerability assessments is a good practice, it does not demonstrate the relationship between vulnerability, threat, and risk.

Focusing on physical security and firewall configurations focuses on risk mitigation techniques but does not illustrate the interplay between vulnerability, threat, and risk.

While hiring external cybersecurity expertise can be part of a comprehensive security strategy, this choice does not demonstrate the relationship between vulnerability, threat, and risk.

q_dev_vuln_zero-day_03_secp8

A major software vendor becomes aware of a new zero-day vulnerability in one of its products due to an anonymous tip. The vulnerability could potentially allow unauthorized access to sensitive data stored in the software.

The vendor is currently creating a patch to address the issue.

Which of the following BEST describes the current risk to the software users and the appropriate response from the software vendor?

Answers:

- Since the vendor knows about the vulnerability, there is minimal risk. The vendor should alert all users about the vulnerability immediately and provide mitigation steps.
- ***The risk to the users is significant, and the vendor should quietly create a patch without informing the users until it is ready.**
- There is no risk to users as long as the vendor does not disclose the vulnerability. The vendor should continue its usual operations without interruption.
- The risk to users is unknown, and the vendor should contact individual users to assess potential damage before proceeding.

Explanation:

Zero-day vulnerabilities represent significant risk, and the vendor should prioritize creating a patch. Disclosing the vulnerability to the public before a patch is ready could increase the risk.

Alerting users about the vulnerability could also alert potential threat actors, increasing the risk before a patch is ready.

Even if the vendor does not disclose the vulnerability, there is a risk while the vulnerability exists, especially since someone is aware of it, as indicated by the anonymous tip.

The risk is significant due to the nature of the vulnerability, and contacting individual users is not feasible, nor will it reduce the risk. The vendor should focus on creating a patch.

q_dev_vuln_zero-day_04_secp8

An information security analyst at a tech company reviews a security report outlining recent attack vectors against the company's systems.

The analyst identifies potential risks related to unpatched software vulnerabilities still unknown to the vendor and risks associated with weak cryptographic algorithms. The analyst wants to prioritize these risks to decide on immediate remedial action.

Based on the provided scenario, what BEST describes an unknown vulnerability in software that the vendor has yet to discover or patch, and that attackers are actively exploiting?

Answers:

- ***Zero-day vulnerability**
- On-path attack
- Rainbow table attack
- Public key infrastructure flaw

Explanation:

The term "zero-day" describes a software vulnerability that the vendor has yet to identify. Attackers exploit this vulnerability and jeopardize systems.

In an on-path attack, an attacker intercepts and might alter communication between two parties. However, this threat does not connect to a software vulnerability unpatched and unknown by the vendor.

Attackers crack encrypted passwords using this method, referencing a precomputed table of hash values for possible passwords. This method does not address a software vulnerability that the vendor has not identified or patched.

While issues in public key infrastructure (PKI) introduce vulnerabilities into cryptographic systems, they do not point to an unpatched software flaw unknown to the vendor.

5.8 Network Applications

As you study this section, answer the following questions:

- How does application vulnerability scanning differ from general vulnerability scanning?
- What is package monitoring used for?
- What security measures should you incorporate to control the use of networking software?
- What is static analysis?
- What is dynamic analysis?

In this section, you will learn to:

- Configure application control software.

The key terms for this section include:

Term	Definition
Peer-to-peer (P2P) software	Software that allows users to share content without centralized servers or centralized access control.
Instant messaging	Real-time text messaging communication that supports picture, music, and document exchange.

This section helps you prepare for the following certification exam objectives:

Exam	Objective

CompTIA Security+ SY0-701	4.3 Explain various activities associated with vulnerability management.
	• Identification methods
	  ○ Application security
	  ▪ Static analysis
	  ▪ Dynamic analysis
	  ▪ Package monitoring

TestOut Security Pro	3.2 Implement Application Defenses 3.2.1 Implement Application Whitelisting 3.2.3 Configure web application security

5.8.1 Network Application Security (Lesson Video)

Transcript:

In this lesson, we'll talk about how applications can pose a threat to your network and how to manage those risks. We start by looking for vulnerabilities.

Vulnerability scanning is a crucial aspect of cybersecurity that aids in identifying weaknesses in a system's security defenses.
Imagine your organization's network and software systems as a secure facility and vulnerability scanning as a diligent guard
searching for weak points in its fence.
To achieve this, cybersecurity professionals use specialized tools like openVAS and Nessus. These tools act as vigilant security guards, examining various aspects of your network and systems. They check for issues such as outdated software, misconfigured settings, and missing patches, which can serve as potential entry points for malicious actors.
However, when it comes to application security, a more tailored approach is needed. Applications are like unique rooms within your secure facility, each with its own vulnerabilities. Traditional vulnerability scanning tools can't fully grasp these intricacies. For this, we turn to specialized application scanners, penetration testing frameworks, and code testing methods.
Application vulnerability scanning is a refined process that zeros in on the specific weaknesses within software applications. Think of it as having an expert locksmith who knows the ins and outs of each room's lock and key.
This scanning method employs two techniques: static analysis and dynamic analysis. Static analysis involves reviewing the application's code without executing it, much like scrutinizing the blueprints of a room. Dynamic analysis, on the other hand, tests the running applications, uncovering issues like unvalidated inputs, broken access controls, and SQL injection vulnerabilities by actively trying to breach the application's defenses.
These vulnerabilities are unique to software applications, and their discovery requires specialized tools and techniques.
Managing these risks necessitates a separate approach from general vulnerability scanning
because applications often follow their own update cycles and have distinct security challenges.
In the complex world of software development, applications often rely on external components, like libraries and dependencies. Imagine these components as pieces of machinery inside your secure facility.
Package monitoring is the process of keeping a watchful eye on these components. It ensures they're up-to-date and free from known vulnerabilities that hackers might exploit. This is essential because just
like a compromised piece of machinery can weaken the security of your facility, outdated or vulnerable software components can jeopardize your application's security.
To achieve this, organizations use automated tools like Software Composition Analysis tools. These tools constantly compare your software inventory against databases of known vulnerabilities, ensuring that your components are sturdy and reliable. They can also suggest updates or replacements when vulnerabilities are discovered.

In addition to automated tools, organizations establish governance policies around software usage. These policies mandate regular audits of software packages, require approvals for new additions, and outline procedures for updating or patching software in case vulnerabilities are identified.
So, think of vulnerability scanning, application vulnerability scanning, and package monitoring as the various layers of security in your facility: one guarding the perimeter, another securing the rooms, and the last ensuring the reliability of the machinery within. Together, they form a comprehensive defense against modern cyber threats.

5.8.2 Configure Application Control Software (Demo Video)

Transcript:

In this demonstration, we're going to look at application control. Application controls focus on controlling the applications a user at a workstation can access over a network. This is similar to what a firewall does.

For example, a packet filtering firewall examines traffic going through it. Based on its rule set, a firewall will block traffic using specific ports or protocols, so you should be able to control application access with a firewall.
However, if you have a savvy user trying to access a forbidden application on the internet, the user can reconfigure the session to use a protocol or port that is commonly left open on most network firewalls, for example, port 80.
A user could reconfigure a game application blocked by the firewall to use port 80. The packet filtering firewall doesn't examine the contents of the packet, only the protocol--TCP, UDP--and the port.
So, a firewall wouldn't block the game traffic redirected to a port that's used for legitimate traffic.
Application control software, on the other hand, focuses on the application signature.
In much the same way that antivirus software uses signatures to detect viruses on your system, application control software uses application signatures to identify traffic associated with a specific application.
It disregards the port number used.
In this demonstration, we're going to configure application control software to block specific network applications.
To do this, we have our network set up similar to what is shown in this picture here, with user computers accessing the network through a shared switch--some wirelessly, some wired--and ultimately passing through the firewall that also has application control software configured on it, to our router, and then out to the internet.
In other words, all traffic passes through here; and as such, the application control software can look at those packets before it allows entry or exit from the network.
For this demo, we'll be using the untangle software that includes an application control module. Certain aspects of this program are free. You have to pay for the application control, but you can try it out for free for 14 days.
You can click up here to see what applications are currently installed. You can see there's a variety of applications or modules that they have.
We have captive portal, which requires, for instance, users to accept a use agreement before getting onto our network; there's a firewall; there are some phishing blockers or virus protection.
We're interested in this application control. Even though the application control is up and running and turned on, it's actually not filtering much. Before we can use it, we need to tell it which applications we would like to filter.
In order to demonstrate this, before I configure that, I want to show you that I have access on a machine that's within my network. I'm going to switch over to my Windows 10 machine now.
My Windows 10 machine is one of these computers over here. Let's go look at it now. As you can see, my Windows 10 machine has access to the internet right now.
We can go out and do a Google search on application controllers--or, in this case, a Bing search--and you can see it returns results.
Perhaps I want to check Facebook and see what's going on in my life, or I could pull up Skype and start to chat my life away on Skype. You can see that these applications are working.
Let's go ahead now and switch back to our application control and enable some rules to prohibit access to these services. We'll come here to the Applications tab, and then we need to go down and find those specific services.
You can see there's a wide variety of services that are listed here. I wish there was a better way to search for the particular service that you're wanting to block. For now, we'll have to be content with just scrolling down. Look at the thousands, over 2000 different applications, that you can block.
So, I find Facebook here and I'm going to go ahead and block that. I could also flag it so that it ends up in one of my reports.

This Tarpit option right here, simply allows the connection to be established, but then the application control 'software untangle' drops the information so that both sides think there's a connection, but no data actually gets through. We blocked Facebook.
Let's go ahead and scroll down and block Skype now. There's lots of different Skype services. I'm going to just block them all. You can see that it's fairly granular in what you can do, allow or prohibit.
Once you're done, then you need to click the Save button. Unfortunately, the application doesn't scale well, so you'll have to scroll down to get to that Save button. There it is right there.
Once you've clicked that Save button, now those applications and those rules will be enforced. Let me now switch back over to my Windows 10 environment and see the impact of those rule changes.
Let's go ahead and try to refresh Facebook. You'll notice that nothing works. As we refresh Facebook, you see that the page can't be reached. However, other pages are still accessible, and we can still do our search.
Let's go investigate Skype now. You can see here that my contacts are no longer online, and it's having trouble connecting over there.
Again, you can get pretty granular on what you want to block and what you want to allow. Let's switch back over to the untangle server now. You can see how effective that was in blocking the traffic.
We can go look and it monitors how many sessions are there. Looks like it had 2500 scans and allowed 1700 of those. It flagged 70 different applications, kept track of those.
You have kind of a dashboard around what it has done. You can easily turn this on and off by simply clicking right here.
And then if we switch back over to our Windows 10, you'll see that all of a sudden I can now access Skype and Facebook. Let's do that. No problem. And if we pull up Skype, you can see that it's back online.
Switching back over to our untangle server', let's just look at a couple more things.
This first column is just the application signature. You can see the name, the category.
This is nice because you can ban whole groups of applications based on the type of category, or the presumed productivity associated with that application, risk associated with it, and then a short description of that. There are others.
You can go look at the specific roles, or you can view reports behind this. So, once again, very easy to set up, but very useful in helping to control your environment, and what's going on within your enterprise.
That's it for this demonstration. In this demo, we introduced you to application control software. We first talked about what application control software does.
We then configured the untangle application control software to block specific traffic--in this case, Skype and Facebook.
Then we went to the client system on the internal network and we tried to access a forbidden application and it was blocked.

5.8.3 Network Application Facts

This lesson covers the following topics:

- Vulnerability scanning
- Application vulnerability scanning
- Package monitoring
- Managing networking software

Vulnerability Scanning

Vulnerability scanning supports application security, as it helps to locate and identify misconfigurations and missing patches in software. Advanced vulnerability scanning techniques focused on application security include specialized application scanners, pen-testing frameworks, and static and dynamic code testing.

Vulnerability scanning tools like openVAS and Nessus are popular tools offering a broad range of features designed to analyze network equipment, operating systems, databases, patch compliance, configuration, and many other systems. While these tools are very effective, application security analysis warrants much more specialized approaches. Several specialized tools exist to more deeply analyze how applications are designed to operate and can locate vulnerabilities not typically identified using generalized scanning approaches.

Application Vulnerability Scanning

Application vulnerability scanning describes a specialized vulnerability scanning method for identifying software application weaknesses. This includes static analysis (reviewing application code without executing it) and dynamic analysis (testing running applications), which can identify issues like unvalidated inputs, broken access controls, and SQL injection vulnerabilities. Application vulnerability scanning is typically handled separately from general vulnerability scanning due to the unique nature of software applications and the specific types of vulnerabilities they introduce. General vulnerability scanning is designed to detect system-wide or network-wide weaknesses, such as out-of-date software or misconfigured firewalls.

In contrast, application vulnerability scanning evaluates the coding and behavior of individual software applications. It looks for issues like cross-site scripting (XSS), SQL injection, and insecure direct object references unique to software applications. These application-specific vulnerabilities require specialized tools and techniques to identify and mitigate and are generally different from the scanning tools used in general vulnerability scanning. Applications frequently have their own release and update cycles, separate from the rest of the environment, necessitating a more targeted vulnerability management process.

Package Monitoring

Another important capability in application vulnerability assessment practices includes package monitoring. Package monitoring is associated with vulnerability identification because it tracks and assesses the security of third-party software packages, libraries, and dependencies used within an organization to ensure that they are up-to-date and free from known vulnerabilities that malicious actors could exploit. Package monitoring is associated with the management of software bill of materials (SBOM) and software supply chain risk management practices.

In an enterprise setting, package monitoring is typically achieved through automated tools and governance policies. Automated software composition analysis (SCA) tools track and monitor the software packages, libraries, and dependencies used in an organization's codebase. These tools can automatically identify outdated packages or packages with known vulnerabilities and suggest updates or replacements. They work by continuously comparing the organization's software inventory against various databases of known vulnerabilities, such as the National Vulnerability Database (NVD) or vendor-specific advisories.

In addition to these tools, organizations often implement governance policies around software usage. These policies may require regular audits of software packages, approval processes for adding new packages or libraries, and procedures for updating or patching software when vulnerabilities are identified.

Managing Networking Software

Use the following to control the use of networking software:

- Have a written policy that identifies the allowed or prohibited usage of all software.
- Use Group Policy or other methods to prevent installation of the software.
- Block firewall ports that are used by the software.
- Consider implementing an application control solution.
    - A firewall alone may be insufficient in blocking the use of network applications.
        - Knowledgeable users can circumvent firewall ACLs by reconfiguring network applications to use ports commonly left open.
        - Packet filtering firewalls do not inspect the contents of a packet. Only the source IP address, destination IP address, protocol, and port are used to determine if a packet should be blocked.
    - An application control solution can be used to block unauthorized network applications.
        - Application control implementations use application signatures to identify specific applications.
        - The contents of packets are inspected and compared against these signatures to identify the associated application.
    - An application allow list is defined centrally and applied to all network devices.
        - Only applications contained in the allow list are allowed.

        - Several actions can be applied to applications that are not on the allow list:
            - Flagged applications are allowed, but a violation is logged when they are identified.
            - Blocked applications are not allowed and are blocked. The session is dropped if it uses UDP and reset if it uses TCP.
            - Tarpitted applications are not allowed. However, the connection between hosts is kept alive while the application data itself is silently dropped. This makes it appear to both hosts that the other host is receiving the data but not responding.

              Not all application control solutions support tarpitting application traffic.

    - If a user tries to use a disallowed application, they can be prompted to contact the help desk or system administrator to get the application reviewed and approved for use.

5.8.4 Practice Questions (Section Quiz)

q_net_app_allow_list_secp8

As the IT manager of a company, you've decided to implement an application allow list to enhance network security and control software usage.

What is the MOST effective way to proceed?

Answers:

- Implement the allow list immediately and block all applications not on the list without informing the employees.
- Create the allow list based solely on the IT department's preferences without consulting other departments.
- ***Implement the allow list, inform employees about the change, and provide a process for requesting additions to the list.**
- Implement the allow list but allow employees to install and use applications not on the list if they feel it's necessary.
- Create an allow list but do not enforce it, leaving it as a guideline for employees.

Explanation:

Implement the allow list, inform employees about the change, and provide a process for requesting additions to the list is the most effective as it ensures that the allow list is implemented and adhered to, while also providing a clear communication channel for employees. By allowing employees to request additions to the list, you ensure that necessary software isn't inadvertently blocked, and you maintain a level of flexibility.

Implementing the allow list immediately and blocking all applications not on the list without informing the employees could lead to confusion and frustration among employees. It's important to communicate changes and provide clear guidelines.

Creating the allow list based solely on the IT department's preferences without consulting other departments could lead to essential software being blocked, hindering productivity. It's important to consult with all departments to ensure necessary software is included in the allow list.

Implementing the allow list but allowing employees to install and use applications not on the list if they feel it's necessary undermines the purpose of the allow list and could lead to security vulnerabilities.

Creating an allow list but not enforcing it, and leaving it as a guideline for employees does not effectively control software usage and could lead to continued unauthorized software usage and potential security risks.

q_net_app_monitor_software_usage_secp8

As a company grows, so does its attack surface and the desirability for a malicious actor to compromise its systems. A company must monitor all software usage, secure applications, third-party software, libraries, and dependencies to keep systems secure.

What are some ways to BEST accomplish this? (Select two.)

Answers:

- ***Implementing application vulnerability scanning**
- ***Using package monitoring**
- Ignoring software updates and patches
- Relying solely on firewall protections
- Allowing all employees unrestricted access to install and use any software

Explanation:

The following are the best answers (most correct):

- Application vulnerability scanning is a specialized method for identifying weaknesses in software applications. It includes static analysis, which involves reviewing application code without executing it, and dynamic analysis, which involves testing running applications. These methods can identify issues such as unvalidated inputs, broken access controls, and SQL injection vulnerabilities. By identifying these vulnerabilities, a company can take steps to address them and thereby enhance its system security.
- Package monitoring involves tracking and assessing the security of third-party software packages, libraries, and dependencies. Automated software composition analysis (SCA) tools can be used for this purpose. These tools can identify outdated packages or packages with known vulnerabilities, and suggest updates or replacements. By keeping these elements up-to-date and free from known vulnerabilities, a company can reduce its attack surface and enhance its system security.

The following are not the best (or incorrect) answers:

- Ignoring software updates and patches is incorrect because software updates and patches often address known vulnerabilities. Ignoring them means leaving these vulnerabilities unaddressed, which increases the company's attack surface and makes its systems more susceptible to compromise.
- While firewalls are an important part of system security, relying solely on them is not sufficient. Firewalls primarily control incoming and outgoing network traffic based on predetermined security rules, but they do not inspect the contents of a packet. Therefore, they cannot identify specific applications or block unauthorized network applications. For this reason, application control solutions, which use application signatures to identify specific applications, are also necessary.
- Allowing all employees unrestricted access to install and use any software is incorrect because not all software is secure. Allowing employees unrestricted access to install and use any software increases the risk of installing software with known vulnerabilities or malicious software. Therefore, it is important to have approval processes and regular audits of software packages to ensure that only secure and necessary software is installed and used.

q_net_app_package_tracking_secp8

A system administrator at a software development company is working on integrating package monitoring into the organization's vulnerability management strategy. The administrator aims to track software packages and applications to ensure they remain free from vulnerabilities and continue to support the firm's security framework.

As the system administrator incorporates package monitoring into the vulnerability management process, which actions will MOST likely get prioritized to enhance the effectiveness of this approach? (Select two.)

Answers:

- ***Tracking outdated software packages**
- Manually updating software every day
- ***Monitoring software repositories for new updates**
- Buying the latest antivirus software every month
- Block firewall ports that are used by the software.

Explanation:

Keeping track of outdated software packages is vital since they can often become targets for attackers if they contain vulnerabilities that newer versions have fixed.

Regularly checking software repositories helps administrators stay informed about the latest updates and patches, ensuring the organization's software remains current and less susceptible to known vulnerabilities.

While regular software updates are crucial, manual daily updates can be excessive and may disrupt operations. Instead, administrators should set a balanced update schedule based on the software's criticality and vulnerabilities.

Regularly updating antivirus definitions is crucial, but purchasing entirely new antivirus software every month is unnecessary and not directly related to package monitoring in vulnerability management.

While blocking firewall ports is an important part of managing networking software, it has no direct impacting on package monitoring.

q_net_app_patch_secp8

A cybersecurity analyst for a large organization permits employees to use instant messaging (IM) services on their devices. Despite using encryption, the analyst's concern is the potential software vulnerabilities and difficulty scanning messages and attachments for threats. Which actions should the cybersecurity analyst use to address this concern?

Answers:

- ***Regularly update and patch the instant messaging apps to address any known software vulnerabilities.**
- Disable all instant messaging services on Windows, Android, and iOS devices to prevent any potential security risks.
- Implement additional encryption layers on top of the existing instant messaging (IM) services to enhance security further.
- Allow employees to use instant messaging services without any changes since the encryption already provides sufficient security.

Explanation:

The recommended action is regularly updating and patching the instant messaging apps to address any known software vulnerabilities. While encryption offers added security, keeping the apps up-to-date is crucial to mitigating potential risks.

Disabling all instant messaging services may hinder employee communication and collaboration, possibly affecting productivity.

Implementing additional encryption layers may introduce complexity and compatibility issues, and the existing encryption already provides a considerable amount of security.

Assuming that the encryption alone provides sufficient security may overlook the importance of addressing potential software vulnerabilities through regular updates and patches.

q_net_app_sbom_sca_secp8

Which of the following are important practices in application vulnerability assessment to ensure the security of third-party software packages, libraries, and dependencies used within an organization?

Answers:

- ***SBOM**
- ***SCA**
- VPN
- SSL
- DHCP

Explanation:

The following are the correct answers:

- SBOM stands for Software Bill of Materials. It is a list of components in a piece of software. SBOMs contribute to software transparency and allow for the identification and management of open source components and third-party software dependencies, which in turn helps to identify known vulnerabilities and manage software supply chain risks.
- SCA stands for Software Composition Analysis. It is a method used to identify open source components and third-party software dependencies in a codebase, and to detect known vulnerabilities in them. By continuously comparing the organization's software inventory against various databases of known vulnerabilities, SCA tools can suggest updates or replacements for outdated packages or packages with known vulnerabilities.

VPN stands for Virtual Private Network. While VPNs are important for securing internet connections and protecting data in transit, they do not directly contribute to the management of third-party software packages, libraries, and dependencies.

SSL stands for Secure Sockets Layer. It is a protocol for establishing encrypted links between a web server and a browser in online communications. While SSL is important for securing data in transit, it does not directly contribute to the management of third-party software packages, libraries, and dependencies.

DHCP stands for Dynamic Host Configuration Protocol. It is a network protocol that enables a server to automatically assign an IP address to a computer from a defined range of numbers configured for a given network. While DHCP is important for managing network configurations, it does not directly contribute to the management of third-party software packages, libraries, and dependencies.

q_net_app_signature_secp8

What do application control solutions use to identify specific applications?

Answers:

- Flags
- Whitelists
- Packet inspection
- ***Application signatures**

Explanation:

Application control implementations use application signatures to identify specific applications.

Group Policy is used to define security policies on a Windows operating system. Application control systems do not use group policies to identify specific applications.

Whitelists are used to define which applications are allowed on network devices.

Packet inspection is performed by firewalls, not application control solutions.

q_net_app_tarpit_secp8

You have implemented a new application control solution. After monitoring traffic and use for a while, you have noticed an application that continuously circumvents blocking.

How should you configure the application control software to handle this application?

Answers:

- Block
- Flag
- ***Tarpit**
- Drop

Explanation:

When using tarpit, the connection between hosts is kept alive while the application data itself is silently dropped. This makes it appear to both hosts that the other host is receiving the data but is not responding. Some malicious applications notice they are being blocked and circumvent the issue. Using tarpit prevents the application from realizing it has been blocked and stops it from circumventing security controls.

Blocked applications are not allowed and are blocked. The session is dropped if it uses UDP and is reset if it uses TCP.

Flagged applications are allowed, but a violation is logged when they are identified.

Drop is not a application control software configuration option.

q_net_app_training_secp8

You are the IT manager of a company that develops its own software applications. You've been tasked with enhancing the security of these applications. You decide to implement application vulnerability scanning.

What is the MOST effective way to proceed?

Answers:

- Implement application vulnerability scanning only for applications that have previously been compromised.
- Implement application vulnerability scanning without informing the development team.
- ***Implement application vulnerability scanning and provide comprehensive training to the development team on the process and how to address identified vulnerabilities.**
- Implement application vulnerability scanning but ignore minor vulnerabilities identified.
- Implement application vulnerability scanning and immediately halt all development activities until all identified vulnerabilities are addressed.

Explanation:

Implementing application vulnerability scanning and providing comprehensive training to the development team on the process and how to address identified vulnerabilities is the most effective way to proceed as it not only introduces a method to identify vulnerabilities but also ensures that the development team is equipped to address these vulnerabilities. Training and clear communication are key to ensuring that the solution is used effectively and that vulnerabilities are properly addressed.

Implementing application vulnerability scanning only for applications that have previously been compromised could leave other applications exposed to potential vulnerabilities. It's important to scan all applications to ensure comprehensive security.

Implementing application vulnerability scanning without informing the development team could lead to confusion and resistance among the development team. It's important to communicate changes and provide clear guidelines.

Implementing application vulnerability scanning but ignoring minor vulnerabilities identified could leave the applications exposed to potential security risks. Even minor vulnerabilities can be exploited and should be addressed.

Implementing application vulnerability scanning and immediately halting all development activities until all identified vulnerabilities are addressed is not very effective. While addressing vulnerabilities is important, halting all development activities could disrupt the company's operations. It's important to find a balance between addressing vulnerabilities and maintaining productivity.

q_net_app_vuln_scan_secp8

Which of the following security actions represents a non-intrusive scanning type of framework?

Answers:

- ***Vulnerability scanning**
- Penetration testing
- Access control list (ACL)
- Keylogger

Explanation:

Whether they use purely passive techniques or some sort of active session or agent, vulnerability scanners represent a non-intrusive scanning type. The scanner identifies vulnerabilities in its database by analyzing things such as build and patch levels or system policies.

Penetration testing that uses exploitation frameworks are "active" and "intrusive" and detectable.

An ACL is a list of permissions associated with a network object, such as a router or a switch, that controls traffic at a network interface level. An ACL is not a type of framework.

A keylogger is spyware that actively attempts to steal confidential information by recording keystrokes. The attacker will usually hope to discover passwords or credit card data. It is not a framework in itself.

q_net_app_white_secp8

You are implementing a new application control solution.

Prior to enforcing your application whitelist, you want to monitor user traffic for a period of time to discover user behaviors and log violations for later review.

How should you configure the application control software to handle applications not contained in the whitelist?

Answers:

- Block
- ***Flag**
- Tarpit
- Drop

Explanation:

When using an application control solution, an application whitelist is defined centrally and applied to all network devices. Only applications contained in the whitelist are allowed. Applications not whitelisted can have several actions applied:

- Blocked applications are not allowed. The session is dropped if it uses UDP and reset if it uses TCP.
- Flagged applications are allowed, but a violation is logged when they are identified.
- Tarpitted applications are not allowed. However, the connection between hosts is kept alive while the application data itself is silently dropped. This makes it appear to both hosts that the other host is receiving the data but not responding.

Not all application control solutions support tarpitting application traffic.

5.9 Switch Security and Attacks

As you study this section, answer the following questions:

- How are switches indirectly involved in Address Resolution Protocol (ARP) poisoning?
- How does the attacker hide his identity when performing media access control (MAC) address spoofing?
- What is the function of a trunk port?
- How is port security different from port filtering?
- What are some important considerations when deciding which secure protocols to implement?

In this section, you will learn to:

- Harden a switch.
- Secure access to a switch.
- Use best practices to ensure switch security.

The key terms for this section include:

Term	Definition
Virtual LAN (VLAN)	A logical grouping of computers based on switch port.
MAC filtering/port security	A switch feature that restricts connection to a given port based on the MAC address.
Port authentication	A switch feature that follows the 802.1x protocol to allow only authenticated devices to connect.
Content-addressable memory (CAM) table	A table maintained by a switch that contains MAC addresses and their corresponding port locations.
Dynamic Host Configuration protocol (DHCP) snooping	A security feature on some switches that filters out untrusted DHCP messages.
Dynamic ARP Inspection (DAI)	A security feature on some switches that verifies each ARP request has a valid IP to MAC binding.
MAC flooding	An attack that overloads a switch's MAC forwarding table to make the switch function like a hub.
ARP spoofing	An attack in which the attacker's MAC address is associated with the IP address of a target's device.
VLAN hopping	An attack in which the source MAC address is changed on frames sent by the attacker.
Double tagging	An attack in which the attacking host adds two VLAN tags instead of one to the header of the frames that it transmits.
MAC spoofing	An attack in which the source MAC address is changed in the header of a frame.
Dynamic Trunking Protocol (DTP)	An unsecure protocol that could allow unauthorized devices to modify a switch's configuration.

This section helps you prepare for the following certification exam objectives:

Exam	Objective

CompTIA Security+ SY0-701	4.1 Given a scenario, apply common security techniques to computing resources.
	• Hardening targets
	  ○ Switches
	4.5 Given a scenario, modify enterprise capabilities to enhance security.
	• Implementation of secure protocols
	  ○ Protocol selection
	  ○ Port selection
	  ○ Transport method

TestOut Security Pro	2.2 Harden Network Devices 2.2.1 Configure and access a switch

5.9.1 Switch Features (Lesson Video)

Transcript:

In this lesson, I'm going to discuss switches and some of their features. This isn't meant to be an exhaustive discussion of switch configurations. Instead, I'll cover topics that can affect your network security. As you probably already know, a switch is a connectivity device that provides communication between different network devices. Switches often use a wired communication medium such as twisted pair and fiber optic to carry the signaling to and from their connected devices. Switches are full-duplex discretionary interconnects that send information only to the intended recipient. I'll explain all of this further in this lesson.

First, let's talk about how a switch works. Every device that connects to a network, whether wired or wireless, has a unique identifier called a Media Access Control address, or MAC address. The MAC address is a 48-bit number separated into six 2-byte numbers. The first 24 bits represent the device manufacturer. In this example, 18-66-DA represents Dell, Inc. The last 24 bits are a random sequential number assigned by the manufacturer to ensure that each device has a unique MAC address. When referencing the OSI model, a MAC address is a layer 2 address and the data that traverses the wire is called a frame. The switch keeps track of the MAC address to which it's connected. Inside every switch is a table of MAC addresses and the port the device is plugged into. This is called the MAC address table. As data traverses the switch, it builds this table based on the frames passing through it. This process continues until all devices connected to the switch are accounted for and the MAC address table is complete. When the MAC address table is complete, the switch can send data directly to the appropriate end device since the table defines which port each device is connected to.
It's also important to know that switches are full-duplex devices. This means they can send and receive data simultaneously. This, along with the data separation by port, means that the chance of an Ethernet collision happening is reduced significantly and speed and efficiency are increased.
Switches are classified as being either unmanaged or managed. An unmanaged switch is often found in homes and small office networks and provides the ability to connect all your devices. Unmanaged switches, on the other hand, aren't configurable. This is just fine for smaller networks that really don't have a need for much sophistication. But larger networks do need additional capabilities. This is where you'll require a managed switch. Managed switches usually have a web-based or command line interface that lets you configure how the switch functions.
For example, a switch's configuration tools let you create and manage virtual LANs, or VLANs. VLANs segment data into different zones. This segmentation might be required for such things as voice, surveillance, and storage. Or it could simply separate zone data for additional resiliency and privacy. Managed switches also support link aggregation, which

provides the ability to combine multiple switch ports in parallel to increase total available bandwidth. This is often used when connecting to devices with multiple NICs that provide things like file and storage services. You can also configure a switch for port security. This lets you define things like which devices and how many can be attached to a single port. A managed switch has many additional benefits that go beyond the scope of this course. But the basic takeaway here is most organizations use managed switches since they can be configured and provide better security.

Another related topic is switch aggregation. Let's look at that a little closer. Often, when you create a switching solution, it's necessary to employ multiple switches throughout a building. There are several reasons for this. The most prevalent is the need to have close proximity to end devices. Ethernet specifications provide for a maximum length of 100 meters between a switch and an endpoint, assuming there are no breaks in the connection such as a wall plate or patch panel. Often, we place wiring closets throughout a building so the 100-meter limit isn't violated.

Normally, an access level switch is placed in the wiring closet to connect a system that's configured for VLANs, port security, and voice over IP. Depending on the number of connections you're dealing with, you might deploy multiple switches for this purpose. These switches are then connected to an upstream switch. The upstream switch is usually much faster and more efficient. Often, the connections between the upstream switch and the access switches are fiber optic, which doesn't have the same distance limitations as a twisted pair of Ethernet cables. In addition, fiber-optic connections are much faster than twisted-pair Ethernet connections.

When you make your decision on the type of switch to purchase, you'll have to choose between a layer 2 and layer 3 switch. While you use both switches to connect end devices to a network, they each have different features.

For example, as the name implies, a layer 2 switch operates at the second layer of the OSI model, which is the Data Link layer. This means the switch understands the connected end devices' physical or MAC addresses. At this level, data passing through switches are known as frames. The port used to send data to an end device is determined by that device's MAC address.

A layer 3 switch operates at the third layer of the OSI model, which is the Network layer. These types of switches can perform the same functions as layer 2 switches. But in addition, a layer 3 switch is aware of the end device's IP address. At the Network layer, the data passing through the switch is known as a packet. A layer 3 switch is also capable of limited IP routing, meaning that layer 3 routers are often used to route packets to and from different VLANs. In practice, Layer 3 switches aren't intended for connecting end devices. Instead, we typically use them for upstream switches.

Now that you understand the basic functions of a switch, let's discuss switch security. Just like any network device, threat actors try to exploit any weakness they can. Switches are no exception. Attackers can use a variety of techniques to compromise switches to gain access to a system.

As such, it's important for system administrators to take precautions and disable switch functions that aren't in use and to monitor switch activity. Three security issues to look out for are MAC flooding, switch spoofing, and ARP poisoning. Let's look at each.

We went over how a switch maintains a table of MAC addresses and the ports to which they're connected. A switch maintains enough memory to store that data and not much more. Knowing this, an attacker might try to flood the switch with bogus MAC addresses. This pushes the legitimate MAC address out and fills up the switch's memory. In effect, this breaks the switch. When the memory is full, the switch reverts to an open state where data is sent to all connected devices. This means that any device connected to the switch is able to capture all data coming out of it. After launching a successful MAC flooding attack, a malicious user can use a packet analyzer to capture sensitive data being transmitted between computers. This wouldn't be possible were the switch operating normally.

Now, let's look at switch spoofing. As we've already discussed, VLANs are used in most organizations to segregate data. Basically, a single network can be broken into smaller chucks using VLAN segmentation. While this is a good practice, it can potentially lead to problems if not done correctly. An attacker could use a less secure segment to access a more secure one. We often configure switches to host multiple VLANs so that end devices that are connected to the right VLAN can communicate with other devices on their individual segment.

Switches eventually do need to communicate with other switches, though. To do this, the switches must be able to transfer information across all VLANs. Someone needs to configure a port as a trunk port, which is then connected to the receiving switch's trunk port. By default, trunk ports have access to all VLANs and pass traffic for multiple VLANs across the same physical link. The attacker takes advantage of this by using Dynamic Trunking Protocol messages, or DTP messages, to spoof itself as a switch. After they accomplish this, the attacker is able to capture all data for all the attached VLANs. One way to prevent a switch spoofing attack is for you to turn off trunking on all ports except the ones that require it. In addition, you should disable DTP on ports that do require trunking, and manually enable the trunking yourself.

The last switch security issue we'll discuss is known as ARP poisoning. Address Resolution Protocol, or ARP, associates a device's MAC address with the IP address assigned to it. To aid in this process, an ARP table is created and stored in a switch's memory for easy lookup. Knowing this, attackers send commands to the switch to overwrite the switch's ARP

table contents by replacing a good, known MAC address with the attacker's device's MAC address. As a result, data that was intended for the legitimate device is now sent to the attacker's device. In many cases, the attacker captures the data and sends it on to its rightful owner. This is known as an on-path attack.
ARP poisoning attacks are difficult to mitigate. If an attacker has access to the internal network, there's little an administrator can do. Specialized training might be a good idea to help you avoid this type of attack. When you work over the internet, you should try to use virtual private networks, or VPNs. VPNs use an encrypted tunnel that largely blocks your activity from ARP spoofing.
That's it for this lesson. This lesson introduced many features we have available on modern switches. We discussed how a switch works, how you can aggregate switches, and the differences between a layer 2 and a layer 3 switch. We ended this lesson by discussing three potential security concerns, which are MAC flooding, switch spoofing, and ARP poisoning.

5.9.2 Securing Network Switches (Lesson Video)

Transcript:

In this lesson, I'll discuss several of the best practices you can implement to help secure your network switches. I'll also cover additional topics that further lock down a switch and add additional controls to make it more secure and less susceptible to an attack. These topics include port security, DHCP snooping, and dynamic ARP inspection.

The first best practice in securing a switch is to change the switch's default credentials. When doing so, choose a username that's not too easy to guess and a complex password using lower and uppercase characters, numbers, and non-alphanumeric symbols.
You should enable secure shell, or SSH, for remote access and also disable telnet. Telnet uses cleartext for usernames and passwords, which isn't good. When it comes to securing a switch, Simple Network Management Protocol, or SNMP, is a powerful ally when you configure it correctly. When it's left unconfigured, though, it presents a security vulnerability that can simply be avoided by disabling it. In the unlikely event there are switch ports left open with no connection, ensure those ports are disabled to prevent unwanted connections.
In addition, you should add a warning banner that states that unauthorized switch configuration access is prohibited. The last best practice is to enable logging. This allows administrators to see any major or minor events a switch experiences. You can also use a logging server to store, archive, and consolidate logging for the enterprise.
Now, let's shift gears to port security. It's up to the switch manufacturer to define how switch security is implemented and the command syntax that's used for setup and configuration. But you can use port security as more granular approach to switch security. Port security configurations can limit the number of devices allowed per port, limit hardware address connections, and define what happens when the port experiences a violation of these settings. For example, you could set it to shut down after a breach. An important note here is that on many switches, port security can't be configured on trunk, EtherChannel, or port analyzer ports.
Since organizations face constant battles with finding open switch connections in a growing workforce, one solution is to add an intermediate switch. In this case, a small switch is placed in a small office that allows several connections, and then that switch is connected to the upstream switch. If the number of devices is limited on the upstream switch and set to one, only the first device that tries to connect is allowed a connection. When the second device tries to connect, the switch denies the connection and the second device won't connect to the network
You can also configure switch ports to only accept connections from specific MAC addresses.
For example, let's configure port 1 for the MAC address ending in BA, and port 2 for the MAC address ending in 45. Assuming the devices connected to those ports match the required MAC address, they're
allowed to connect. While this is a good defense, it's difficult to maintain and very simple to defeat if one device is swapped out for another. The port for that device will need to be reconfigured if a new computer is bought or the network card is changed. Likewise, it's very easy to spoof a MAC address on a given system, rendering MAC address security ineffective.
When a port security rule violation occurs, the switch may react differently depending on its configuration. This might be implemented differently by different switch manufacturers, but the actions are usually closely related. For the least restrictive action, the port simply drops frames from the offending device. The port or interface remains operational and nothing is reported in the logs.

Another setting tells the switch to not only drop the frame but send an alert and log the offending operation. The third, most restrictive violation disables the port when a violation is detected. This requires intervention to re-enable the port and is the default violation mode.

There are several additional measures you can take to protect network switches. Many are common sense precautions, such as physical security and the best practices listed earlier in this lesson. Let's discuss two additional security configurations you might consider.

First, is DHCP snooping. DHCP, as a service, dynamically distributes network parameters, such as IP addresses and default gateways to network devices. For example, when you first start a workstation, it automatically requests and receives the IP information from a DHCP server. In this type of environment, the DHCP server is known as a trusted device, in the same way that routers, firewalls, and file servers are trusted. A trusted device simply means that it's managed by an administrator in your company.

Since most organizations use DHCP for dynamic IP address allocation, attackers often try to place a rogue DHCP server on the network in an attempt to provide end devices with forged IP address information to introduce vulnerabilities onto the network. DHCP snooping attempts to prevent this from occurring. But for DHCP snooping to work, it must be enabled on your devices. While the actual configuration for DHCP snooping is beyond the scope of this lesson, it's important to learn which process to use to enable and configure DHCP snooping in your infrastructure. Know that the configuration process will vary by manufacturer. Once configured, the DHCP snooping process detects, blocks, and drops DHCP packets when the DHCP information comes from an untrusted source. This information is also logged so further actions can be taken to locate and eradicate the rouge DHCP server.

Another security feature available on many switches is called dynamic ARP inspection. This feature rejects invalid or malicious ARP packets, which can help prevent on-path attacks.

An on-path attack is when an attacker secretly relays or alters the communication between two parties who believe they're directly communicating with each other. So how does an attacker implement a on-path attack?

In normal operations, ARP tables are used to identify end devices. Once identified, communications can flow between the devices.

So an attacker assumes the identity of both endpoints and inserts themself in the middle of the communication. Let's see how that works. First, they poison the ARP cache of end device B and tell B that he or she is A. Then they tell A that he or she is B. Once completed, the original connection between A and B is replaced with A sending information to M and M forwarding the information to B, and vice versa. At this point, M sees all the communication traffic between A and B. He or she can log the information or change it depending on the intent. Adding dynamic ARP inspection can help to prevent this type of attack.

To do this, first configure DHCP snooping on your switch as we just discussed. Next, you need to enable dynamic ARP inspection, or DAI. Once DAI is enabled and configured, only trusted sources can affect the ARP table. So now the switch drops the ARP packet when an untrusted source, in this case the attacker, tries to poison the ARP table. That's because the sender's MAC address and sender's IP address don't match an entry in the DHCP snooping database.

That's it for this lesson. In this lesson, we discussed several best practices to ensure switch security. Next, we talked about how port security can be used to prevent unauthorized access to a network. We also discussed how you can use DHCP snooping in conjunction with dynamic ARP inspection to thwart rogue DHCP servers.

5.9.3 Switch Security Facts

This lesson covers the following topics:

- Security switch features
- Implement switch security
- Spanning Tree Protocol

Security Switch Features

The following table lists switch features that can be implemented to increase network security:

Feature	Description

Virtual LAN (VLAN)	A virtual LAN (VLAN) is a logical grouping of computers based on switch ports.
	
	• VLAN membership is configured by assigning a switch port to a VLAN.
	• A switch can have multiple VLANs configured on it, but each switch port can only be a member of a single VLAN (see exception described below).
	• VLANs can be defined on a single switch or configured on multiple interconnected switches. With multiple switches, each switch can be configured with the same VLANs, and devices on one switch can communicate with devices on other switches as long as they are members of the same VLAN.
	• A trunk port is used to connect two switches together.
	  ○ Typically, gigabit ethernet ports are used for trunk ports, although any port can be a trunk port.
	  ○ A trunk port is a member of all VLANs defined on a switch and carries traffic between the switches.
	  ○ When trunking is used, frames that are sent over a trunk port are tagged by the first switch with the VLAN ID so that the receiving switch knows to which VLAN the frame belongs.
	  ○ The Trunking Protocol describes the format that switches use for frame tagging with the VLAN ID.
	  ○ Because end devices do not understand the VLAN tags, the tag is removed from the frame by the switch before the frame is forwarded to the destination device.
	  ○ VLAN tagging is only used for frames that travel between switches on the trunk ports.
	• Using VLANs, the switch can be used to create multiple IP broadcast domains. Each VLAN is in its own broadcast domain, and broadcast traffic is sent only to members of the same VLAN.
	• In a typical configuration with multiple VLANs, workstations in one VLAN can not communicate with workstations in other VLANs. To enable inter-VLAN communication, you need to use a router (or an OSI Layer 3 switch).

MAC filtering/port security	With switch port security, the devices that can connect to a switch through the port are restricted. • Port security uses the MAC address to identify allowed and denied devices. • On the switch, MAC addresses are stored in RAM in a table and are associated with the port. The table can be manually configured, or learning devices can automatically build the table. • You can specify that only a single MAC address is allowed per port, or you can configure each port to allow multiple addresses. • With automatic configuration, the next device or specified number of devices can connect to the port and additional devices are denied. • A port violation occurs when an unauthorized device tries to connect. The switch configuration determines how the switch handles frames from an unauthorized device. The switch can either drop all frames from the unauthorized device or shut down the port, disabling all communications through that port.

Port authentication (802.1x)	Port authentication is provided by the 802.1x protocol and allows only authenticated devices to connect to the LAN through the switch. Authentication uses user names and passwords, smart cards, or other authentication methods.

Implement Switch Security

Be aware of the following when implementing switch security:

- Creating VLANs with switches offers many administrative benefits. For example, you can:
  - Create virtual LANs based on criteria such as workgroup, protocol, or service.
  - Simplify device moves (devices are moved to new VLANs by modifying the port assignment).
  - Control broadcast traffic based on logical criteria (only devices in the same VLAN receive broadcast traffic).
  - Control security (isolate traffic within a VLAN).
- When you use switches to create VLANs, you still need routers to:
  - Route data between VLANs.
  - Provide port filtering. Port filtering filters network packets in and out of devices based on their application type or port number.
  - Route data into and out of the local area network.
- VLANs are commonly used with voice over IP (VoIP) to distinguish voice traffic from data traffic. Traffic on the voice VLAN can be given a higher priority to ensure timely delivery.
- MAC filtering uses the MAC address of a device to drop or forward frames through the switch. Port authentication requires that the user or device authenticates before frames are forwarded through the switch.
- In general, all switch ports are enabled by default. To increase the security of the switch and network, you should disable individual ports that are not in use.

Restricting access by MAC address is difficult to manage and still prone to spoofing. Better security is obtained by forcing computers and/or users to authenticate before full network access is granted. The IEEE 802.1X Port-based Network Access Control (P NAC) standard allows a switch to require authentication when a host connects to one of its ports. 802.1X uses authentication, authorization, and accounting (AAA) architecture:

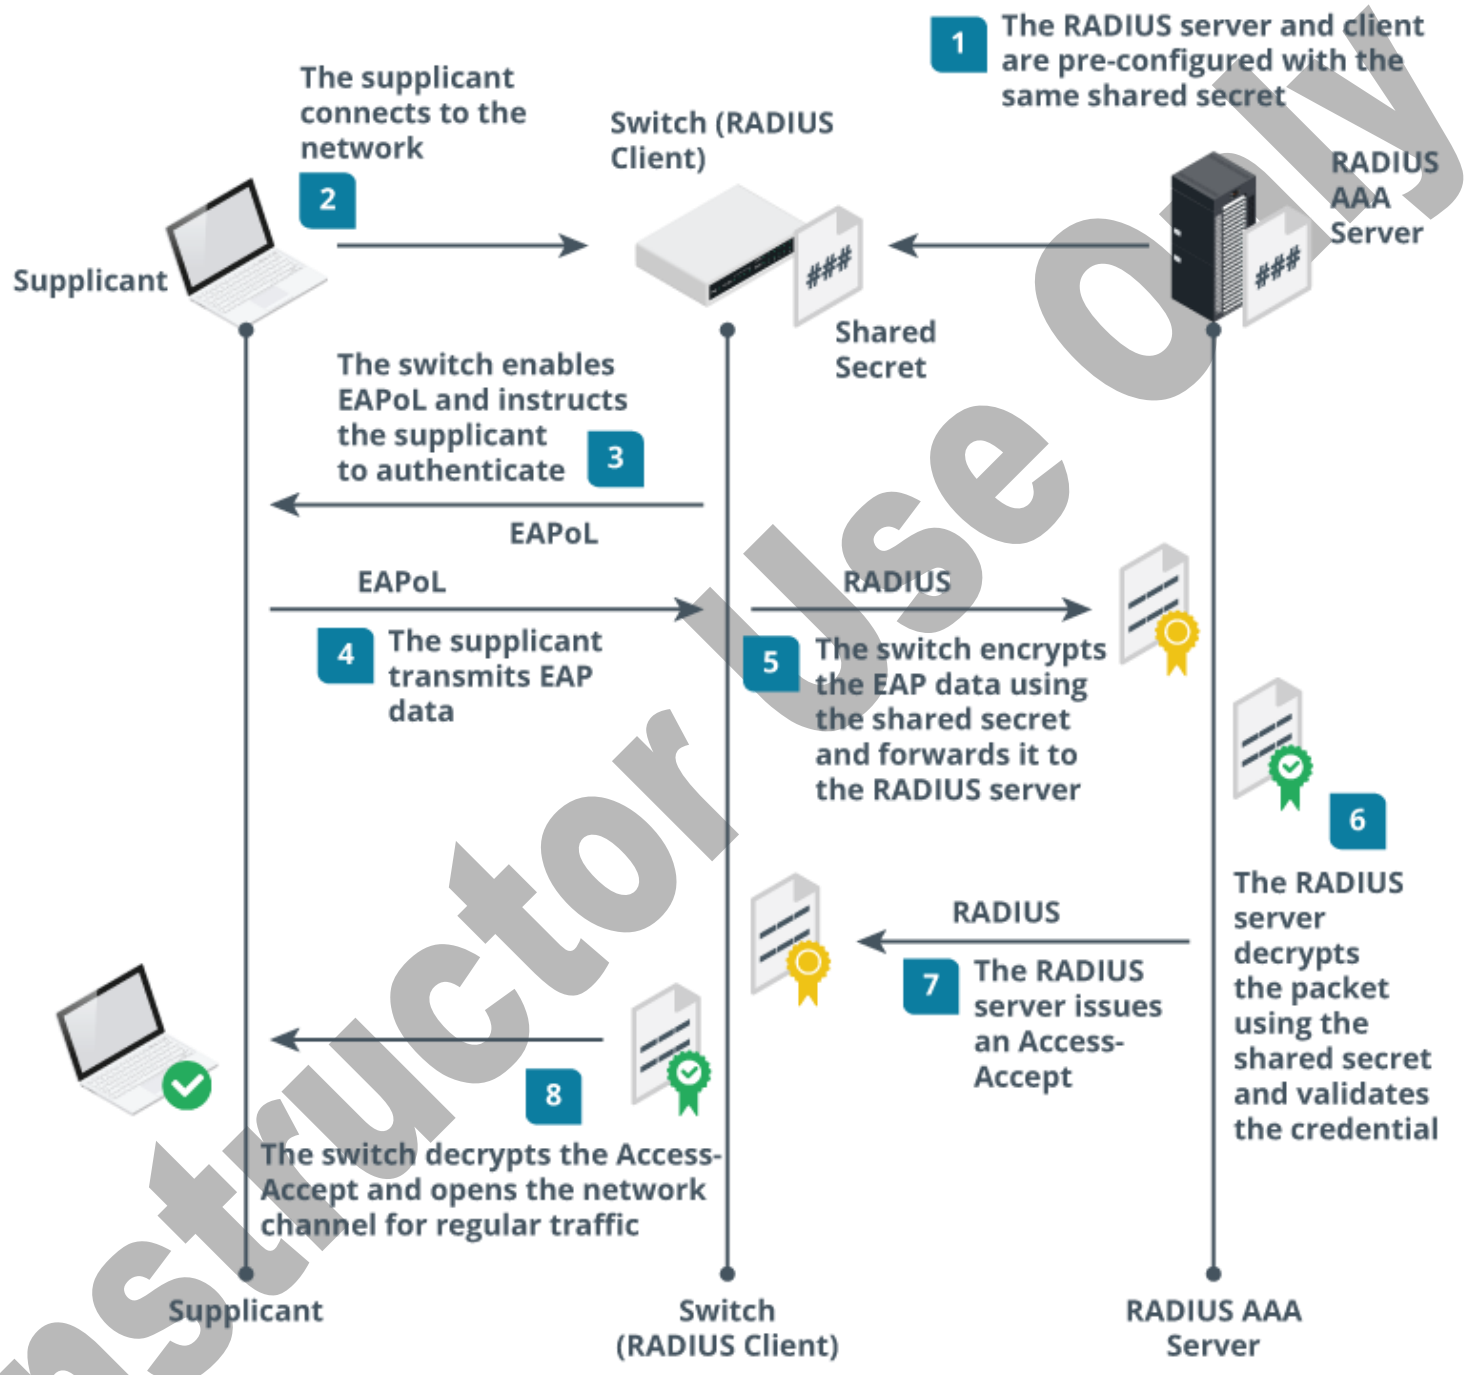
- Supplicant — the device requesting access such as a user's PC or laptop.
- Authenticator — the switching device (or any type of network access appliance). This does not validate authentication request s directly but acts as a conduit for authentication data.
- Authentication server —the server that holds or can contact a directory of network objects and that can validate authentication requests, issue authorizations, and perform accounting of security events.

The 802.1X standard is implemented by two protocols:

- Extensible Authentication Protocol (EAP) — provides a framework for deploying multiple types of authentication methods. It is often used with digital certificates to establish a trust relationship and create a secure tunnel to transmit the user credential or to perform smart-card authentication without a password.
- Remote Authentication Dial-In User Service (RADIUS) —allows the authenticator and authentication server to communicate authentication and authorization decisions. The authenticator is a RADIUS client; the authentication server is a RADIUS server.

When a host connects to an 802.1X-enabled switch port, the switch opens the port for the EAP over LAN (EAPoL) protocol only. The switch port only allows full data access when the host has been authenticated. The switch receives an EAP packet with the supplicant's credentials. These are encrypted and cannot be read by the switch. The switch uses the RADIUS protocol to send the EAP packet to the authentication server. The authentication server can access the directory of user

accounts and can validate the credential. If authentication is successful, it informs the switch that full network access can be granted.



Some hosts are so security-critical that it is unsafe to connect them to any type of network. One example is the root certification authority in PKI. Another example is a host used to analyze malware execution. A host that is not physically connected to any network is said to be air-gapped .

It is also possible to configure an air-gapped network. This means that hosts within the air-gapped network can communicate, but there is no cabled or wireless connection to any other network. Military bases, government sites, and industrial facilities use air-gapped networks.

Physically isolating a host or group of hosts improves security but also incurs significant management challenges. Device administration has to be performed at a local terminal. Any updates or installs have to be performed using USB or optical media. This media is a potential attack vector and must be scanned before allowing its use on an air-gapped host.

Spanning Tree Protocol

To provide fault tolerance, many networks implement redundant paths between devices using multiple switches. However, providing redundant paths between segments causes packets to be passed between the redundant paths endlessly. This condition is known as a switching loop. Switching loops lead to incorrect entries in a MAC address table, making a device appear to be connected to the wrong port and causing unicast traffic to be circulated in a loop between switches. The Spanning Tree Protocol runs on switches to prevent switching loops by making only a single path between switches active at a single time.

The Spanning Tree Protocol also:

- Provides redundant paths between devices.
- Recovers automatically from a topology change or device failure by unblocking redundant paths.
- Identifies the optimal path between any two network devices.
- Calculates the best loop-free path through a network by assigning a role to each bridge or switch and by assigning roles to the ports of each bridge or switch.

The type of ports used by the Spanning Tree Protocol are:

- Root ports, which are configured to communicate directly to the root switch.
- Designated ports, which forward frames to and from attached hosts.
- Blocked ports, which form a loop and are used for redundancy.

Ports in the Spanning Tree Protocol exist in one of five states:

- Blocking
- Listening
- Learning
- Forwarding
- Disabled

5.9.4 Switch Attacks (Lesson Video)

Transcript:

Threat actors look for any opening they can find, and network switches are no exception. Inside attacks take advantage of anything accessible, and attackers can exploit switches to gain valuable information. It's important for you to know that all network information flows through switches and routers, including such things as authentication information and data. Attackers can use a variety of switch attacks methods to gather valuable information that they can use later to exploit the network.

In this lesson, we'll go over the following attack methods: MAC flooding, ARP spoofing, VLAN hopping, STP manipulation, double tagging, and MAC spoofing in regard to Layer 2 switches. Remember, Layer 2 switches understand Ethernet frames at the OSI Data Link layer.
The first attack to examine is MAC flooding. Switches maintain MAC address tables, sometimes called Content Access Memory tables, or CAM tables, to track workstations' and ports' associations. Switches learn which workstation is

connected to each port, and that information is stored in the MAC address table and used when switches forward information.

For example, let's say that Workstation A wants to send information to Workstation D. The frame has a source address ending in As, and the destination address is the address ending with Ds. When A sends the information, the switch examines the destination address and sends the data out port 1 to its destination. Workstations B and C aren't involved, so they never see the information.

Suppose an attacker wants to see all data passing through this switch. Considering that a switch's normal operation only sends data to the intended recipient, the attacker would only be able see data destined for his or her workstation, which is very unlikely. But the attacker can flood the switch with fake MAC address information and fill up the MAC address table. Once the switch can no longer store any more MAC addresses, the switch enters a fail-open mode and behaves the same as a network hub or Layer 1 device. This means that any packet coming in now go out to all switch ports.

The next switch attack is called ARP spoofing, also known as ARP poisoning. But let's first talk about Address Resolution Protocol, or ARP, which works similarly to DNS. DNS resolves a fully qualified domain name into an IP address, while ARP associates a device's MAC address with the IP address assigned to that same device. To aid in this process, a switch creates and stores an ARP table in memory for easy lookup.

Knowing this, an attacker sends commands to the switch to overwrite the contents of its ARP table by replacing a good, known MAC address in the table with the MAC address of the attacker's device. This is the ARP spoofing or ARP poisoning. As a result, data that was intended for the legitimate device is now sent to the attacker's device. In many cases, the attacker captures the data and sends it on to its rightful owner. Another attack method you should know about is VLAN hopping. VLANs are used to separate traffic into sections that function like networks. This is often done to all the different VLANS that carry different types of traffic, such as data, voice, or surveillance information. Since each VLAN is its own network, a device on one VLAN can't communicate with a device on another VLAN without a router. There are a couple of techniques attackers can use to take advantage of this VLAN separation.

The first is VLAN spoofing. VLAN spoofing takes advantage of a switch that's using its default settings, which allows for dynamic trunk negotiation. Depending on the switch, this default setting is known as dynamic auto or dynamic desirable. This means that if you have a switch connected to the original switch, the ports connecting the two are automatically configured as a trunk connection.

A trunk connection allows data from one switch to pass to another. A spoofing attach takes advantage of this by fooling the switch into thinking the attacker is connected using a trunk line. Although there are several ways to carry out a spoofing attach, such as adding a new switch, we'll look at how someone could accomplish a spoofing attach with just one switch.

Our switch here is configured with two VLANs VLAN 10 and VLAN 20 with both having several computers connected to it. Our attacker, a disgruntled employee, is connected to VLAN 10 and wants to steal sensitive information from the company's chief executive officer. But as mentioned, VLAN 10 is a separate network from VLAN 20. So as-is, the attacker can't access the CEO's computer.

By using a tool like Yersinia, our disgruntled employee can send the switch a packet that tells the switch the port he or she is using is really connected to another network switch. This is done using a Dynamic Trunking Protocol frame, or DTP frame. Since the switch is configured to auto-negotiate for a trunk line, it assumes the attacker really is a switch and opens his or her port as a trunk line. With the attacker's port now configured this way, he or she can easily capture packets from the CEO's computer. Keep in mind that the best way to protect your network from this type of attack is to disable the switch's auto-negotiation setting for all ports except those to which an authorized switch is attached.

Another method attackers use is called double tagging. This VLAN hopping technique is used when the attacker's computer is on one VLAN switch, and the target computer is on a VLAN attached to a separate switch. In addition, the switches must be configured to use what's called native VLANs.

When a packet is sent to a switch, it includes what's known as a VLAN tag. This tag's purpose is to indicate which switch should process the frame. For example, you'll notice that both users are on VLAN 10. If User A wants to send data to User B, the frame would include the VLAN tag indicating that the frame was intended for VLAN 10. When the data reaches the switch, the VLAN tag is removed and the packet is sent to its rightful destination.

Double tagging is accomplished by manipulating the frame being sent to include two VLAN tags. So one for VLAN 10 and one for Switch 2, or VLAN 20. When this type of frame is received by VLAN 10's switch, the first VLAN tag is removed. But seeing that the second VLAN tag is referencing VLAN 20, the frame is forwarded to that switch. Then, as it normally would, this switch strips off the second VLAN tag and sends the frame to the victim's VLAN, successfully hopping from one VLAN to another. To prevent double tagging, it's important to make sure that your switches aren't configured to use native VLANs. This is because trunk ports configured with a native VLAN won't apply their own VLAN tag when sending these frames, which lets the attacker's tagged frames to continue as I just described.

Another common switch attack is known as a Spanning Tree Protocol, or STP, manipulation attack. STP is normally configured on a network with several switches. The primary purpose is to prevent switching loops. Often, whether

intentional or not, there are several paths data can take to get from its source to its destination. STP dynamically turns off certain switch ports to ensure that data can't get stuck hopping from switch to switch without ever reaching its intended target.
While STP configuration is beyond the scope of this lesson, it's important to understand that a single switch is designated as the root bridge. The root bridge is an optimized data path's primary source. This is necessary because some switches often connect to other switches to form redundant connections to ensure communications continue even if a switch or port fails. The root bridge is used to pass data from switch to switch since all switches that participate in the tree know where the root bridge is located.
So the root bridge is responsible for calculating the spanning tree from topology changes advertised by non-root bridges. If an attacker can become the root bridge, he or she is then able to see a variety of frames that they normally wouldn't see. To perpetrate this attack, the attacker inserts their switch into the tree and manipulates it to appoint his or her switch as the root bridge. By doing this, he or she can use a sniffer to collect data traversing the network. An attacker accomplishes this manipulation by sending bridge ID frames, or BID frames, with a lower ID than that currently being used by the legitimate root bridge.
There are several step you can take to mitigate this type of attack. First, make sure that attackers can't easily guess which bridge ID number is being used by the legitimate root bridge. Most switches have a default root bridge ID, ensuring that your bridge ID is considerably lower than the default one. If your switch supports it, a second option is to set up Bridge Protocol Data Units Guard, or BPDU Guard. This feature allows an interface to put itself into blocking state when it receives a BPDU packet meant to change the root bridge switch. Your third option is to enable Root Guard on the ports not being used as trunk lines. This keeps ports in their assigned roles. If one of these ports receives a BPDU frame, a sys error is logged and that port is blocked, thwarting the attacker's attempt to change the root bridge.
The last common switch attack to discuss is known as MAC spoofing. MAC spoofing is the process of sending out data from a computer using a MAC address that's different from the MAC address physically hard-coded on a network interface card, or NIC. Although you can't physically change your MAC address, there are tools like Windows Network and Sharing Center in Control Panel, SMAC for Windows, and others that can make an operating system believe that the NIC has a different MAC address. There are several reasons attackers may use this method to attack a network, such as to defeat switch port security.
For example, in some networks, part of a switch's security is the creation of a whitelist of MAC addresses. Only devices with a MAC address in the whitelist can be processed through that switch. If an attacker can use a network sniffer to find a MAC address that's being used by a legitimate host attached to the switch, he or she can change their MAC address to a valid one on the whitelist. Then they've successfully gained access to the switch and any data being transmitted through it.
An attacker could use MAC spoofing to change their MAC address to mimic a targeted system as well. For example, once an attacker has assumed a valid computer's MAC address, he or she could send the switch a MAC update command, changing the MAC address table. Now, the switch sends any data that was destined for the target system to the attacker's system. The important thing to know here is that since it's controlled on the attacker's computer, there really isn't a way to prevent MAC spoofing. If this becomes an issue, you'll need to use techniques at the Application level of the OSI model.
As we end this lesson, you've probably noticed that for any of these attacks to work, the attacker must have physical network access. So physical security is a must! One thing to keep in mind is that for every offense, there's a defense. Administrators can make configuration settings that help to avoid some of these attacks or, at least, notify them something strange is going on.
That's it for this lesson. In this lesson, we examined several methods attackers utilize to exploit switch configuration weaknesses, such as the ones shown here. With each of these attacks, one of the primary goals is to collect information that can be used to exploit vulnerabilities at a later time.

5.9.5 Switch Attack Facts

This lesson covers the following topics:

- Common switch attacks
- Switch hardening
- Implementing secure protocols

Common Switch Attacks

The following table describes common attacks that are perpetrated against switches.

Attack	Description
MAC flooding	*MAC flooding* overloads the switch's MAC forwarding table to make the switch function like a hub. MAC flooding is performed using the following method: 1. The attacker floods the switch with packets, each containing a different source MAC address. 2. The flood of packets fills up the forwarding table and consumes so much of the memory in the switch that it causes the switch to enter a state called *fail open mode* . In fail open mode, all incoming packets are broadcast out to all ports (as with a hub), instead of to the designated port (as a switch normally does). 3. The attacker then captures all the traffic with a protocol analyzer/sniffer.

ARP spoofing/poisoning	*ARP spoofing/poisoning* associates the attacker's MAC address with the IP address of victim's device.
	• When computers send an ARP request for the MAC address of a known IP address, the attacker's system responds with its MAC address.
	• The source device sends frames to the attacker's MAC address instead of the correct device.
	• Switches are indirectly involved in the attack because they do not verify the MAC address/IP address association.
	• A default gateway is a prime target because local traffic goes through a default gateway to get to non-local destinations such as the internet.
	• When the attacker's system MAC address receives packets intended for the default gateway, the attacker can:
	  ○ Forward the packets to the actual default gateway (*passive sniffing*).
	  ○ Modify data in the packets before forwarding it (*man-in-the-middle)* .

MAC spoofing	*MAC spoofing* is changing the source MAC address on frames. The attacker's system sends frames with the spoofed MAC address. The switch reads the source address contained in the frames and associates the MAC address with the port where the attacker is connected. MAC spoofing can be used to: • Bypass 802.1x port-based security. • Bypass wireless MAC filtering. • Hide the identity of the attacker's computer or to impersonate another device on the network. • Impersonate a device on the network to capture frames addressed to that device. • Impersonate a valid device on the network to gain network access. For example, to gain access when the switch is using the MAC address to allow or deny a network connection.

Dynamic Trunking Protocol (DTP)	Switches have the ability to automatically detect trunk ports and negotiate the trunking protocol used between devices. The Dynamic Trunking Protocol is not secure and allows unauthorized devices to possibly modify configuration information. You should disable the DTP services on the switch's end user (access) ports before implementing the switch configuration into the network.

Switch Hardening

Examples of changes designed to improve the security of switches from the default settings include the following:

- Change Default Credentials that are well documented and pose a significant security risk.
- Disable Unnecessary Services and Interfaces on a switch or router. Not every service or interface is needed. For example, services like HTTP or Telnet should be avoided.
- Use Secure Management Protocols such as SSH instead of Telnet or HTTPS instead of HTTP.
- Implement Access Control Lists (ACLs) to restrict access to the switch to only required devices and networks.
- Enable Logging and Monitoring to help identify issues like repeated login failures, configuration changes, and many others.
- Configure Port Security helps limit the devices that can connect to a switch port to prevent unauthorized access.
- Strong Password Policies help reduce the risk of password attacks.
- Physically Secure Equipment like keeping devices in a locked room to prevent unauthorized physical access.

Implementing Secure Protocols

Organizations usually follow formal processes when selecting secure protocols to ensure comprehensive documentation and well-informed decision-making. These processes include assessing risks, reviewing policies, and evaluating the security features of different protocols. Organizations may also consult with technical experts or vendors for recommendations. The outcomes of these processes are documented, which is useful for audits and compliance reviews. Additionally, these process outcomes will typically impact security baselines and configuration management systems.

Selecting protocols, assigning ports, setting transport methods, and other security considerations require careful consideration. The first step requires evaluating the data type used and its sensitivity level. Organizations should select secure protocols like HTTPS, SSH, and SFTP/FTPS for transmitting sensitive or private data. Configuring TCP ports depends on the protocol, as standard ports are associated with specific protocols (HTTP commonly uses port 80, HTTPS uses port 443). While default protocol ports can be changed, doing so may complicate configuration and cause potential accessibility issues.

However, many administrators choose to change standard default ports and a method to obscure them. TCP (Transmission Control Protocol) and UDP (User Datagram Protocol) are two principal transport methods. TCP is connection-oriented and provides reliability, ordering, and error-checking, making it suitable for applications requiring high levels of reliability. UDP is connectionless, making it faster than TCP and more suitable for real-time applications like video streaming, telephony, and gaming, where occasional packet loss is less impactful.

When selecting secure protocols, administrators and analysts must consider suitable encryption levels, authentication methods, existing firewalls or other security equipment, and other factors which may impact the operation of the systems and software they are intended to protect. Ultimately, protocol selection requires an optimum balance among security, maintainability, performance, and cost.

5.9.6 Hardening a Switch (Demo Video)

Transcript:

In this demonstration we'll look at various methods to harden a managed switch. In this case we're using a Cisco Small Business Managed Switch and are logged into the management interface using Internet Explorer. We're authenticated as the Admin User so we can make changes. In this demonstration we'll look at port security, management access, and access control using access control lists, ACLs.

To begin, let's look at port security. When hardening a switch, one of the first things we want to do is shut down any unused ports. Click on Configure Port Settings, which will take us directly to the Port Settings page under Port Management.
On this page we can select one of the unused ports. You'll notice we have several ports here that are either down and unused, or up and used. The ones that are unused are currently down. We want to make sure they're administratively down, meaning they have to be turned on before they can be used. Let's take a look at Port Two. It's down.
Let's scroll to the bottom of the page and click Edit. On this page you'll notice that the Administrative Status of this port is actually up, even though it's operationally down. This means there's nothing plugged into it. To make sure that this port remains down and is not used without permission, we'll set the Administrative Status as Down. Click Apply, Close.
To set all other unused ports as Administratively Down, we'll select Port Two then click Copy Settings. In the Copy Settings window we can list all the ports that we want to be down. In this case, we'll type Three, Six, and Eight through 28. Go ahead and click Apply. All of those ports are now administratively down.
Let's look at Port Three for confirmation. Select Port Three and click Edit. You'll notice on this page that the status Administratively Down. So, the status that we copied from Port Two went to the rest of the ports. Click Close.
By setting the ports that we're not using to Administratively Down, those ports will come up at a down state each time the switch starts up. At the end we'll make sure that we save our Configuration File to the Startup Configuration.
Next, we also want to enable port security. To do that, we'll open the Security Tab and click on Port Security. Under this tab we can configure locking mechanism for each of these ports. We'll click on Port One and select Edit.
On this page you'll notice that we can lock the port, meaning we're going to only allow certain MAC addresses to pass traffic through this port. A Classic Lock means that the first device you connect to that port will be remembered and allowed to pass traffic through this port. You can also select Limited Dynamic Lock, which gives you a variable number from one to 256. Let's change this to four.
Now, if you connect a hub to a specific port on the switch and connect four devices to that, you can allow all four of those devices to talk through that port. No additional devices would be allowed to pass traffic.
We'll go ahead and select the Classic Lock. That will give us one device, and the device will be locked in. If you try to connect a device that is not supposed to be on that port, the Action on Violation determines what happens. The default is to discard the packet. If you connect any other device to the port, the traffic will be ignored.
You can also forward the traffic, or you can shut down the port. That's a little drastic for our purposes. However, if you're extremely cautious about your security and you don't want anybody connecting a device you don't know about, being able to shut down the port is one of the most secure things that you can do.
We'll go ahead and select Discard if it's a device that we aren't sure about. If somebody plugs in a device that's not locked in you can also trap the MAC addresses of the offending device. We've enabled locking for Port One, as well as the classic lock. We're going to discard the frames of any other devices that come onto that port. We'll go ahead and click Apply, Close.
Once again, we can take the settings that we've created for Port One and apply them to the rest of the ports. Scroll down to the bottom and select Copy Settings. In this case, we'll select all of the ports, or Two through 28, and click Apply.
You'll see that the settings that we've created for port security now apply to all 28 ports.
The next piece that we would like to cover is management access. We'll go to Management Access Method and click Access Profiles. In this case, the only profile that's on the machine is the Console Profile, which is the default.
We're going to add a new access profile, so click Add. We'll call this access profile Management. In this Management Profile the very first rule, or Rule One that we want to have will deny all management. We'll go ahead and select Deny and specify all different management methods, and apply it to all interfaces. That will be our first and main rule. We'll go ahead and click Apply, Close.
Now that we've created our Management Profile, we can select Profile Rules. It can seem a little confusing that you create a Management Profile then add a rule to it. We'll go ahead and select our Management Profile, and add another rule. It looks very similar to the page we just used.

For Rule Number Two, we want to allow HTTP access. We want to select all interfaces, but we also only want to allow traffic from a specific workstation or IP address. We'll specify that 192.168.1.200 will be the only workstation allowed to access this port. We'll also input the network mask by typing 255.255.255.0. Alternatively, we can use the prefix length and use the prefix instead. We'll go ahead and click Apply, Close.
We now have a management access rule that denies all traffic, and one access rule which allows us to access the HTTP interface from one specific workstation. But, we're not done yet.
We need to go back to Access Profiles and set the Active Profile. Right now, we don't have an active management profile. Go ahead and select Management. This denies all types of management interfaces with this switch, except for the HTTP access from the one workstation that we have selected.
We're not going to click Apply this time. If we do, we'll probably be locked out of the switch, and we want to make sure that we have access to complete this demo.
Let's go to the next section, and look at firmware updates. Under Administration, File Management we can select Upgrade, Backup Firmware. Part of hardening the device or a computer of any kind is to make sure you have the latest software and patches. You can use browse to select the latest firmware and download it.
In this particular switch, you have to select the Active Image once you've loaded the firmware. You can select Image One or the new image, Image Two, and apply it. Next you'll need to reboot the switch. Once you do that the switch will come back with the latest and greatest software and the best enhancements. This allows you to have the best possible security for this switch. Upgrading firmware for the switch as well as applying patches to any computer is a key element to hardening the switch.
The last aspect of hardening the switch is access control using the ACLs. Let's select Access Control. On this switch, we have various methods of access control. We can use a MAC based ACL. We can use an IPV4 based ACL. And we can also use an IPV6 based ACL. We'll set up a MAC based ACL.
In this case, we don't have an access control list, so we'll go ahead and create one. We want to make sure that nobody can attach game consoles or connect any game to our switch. Type Games as the name of our ACL. Click Apply, Close.
We have the ACL, but to put access control entries, ACE, into this access control list, we need to click the MAC Based ACE Table. It has a slightly different interface, but let's click Add to add an entry to this page.
For our first access control entry, Entry One, we're going to select Deny. We'll select Any for the Destination MAC address. Under Source MAC Address, we're going to select User Defined and put in the address, one of the game consoles, or the prefix of the MAC address, which is used for all devices of the same manufacturer. We'll go ahead and enter 00041F followed by six ones. Under Source MAC Wildcard Mask we'll enter six zeroes followed by six ones.
This says that we only care about the first six digits of the MAC Address. This is preventing any device from the same manufacturer from being connected. We'll go ahead and click Apply.
That creates our first entry into the Access Control List Entry Table. We'll add one more just for demonstration purposes. We'll go ahead and create Priority Two.
Once again, we're going to select Deny, and specify the Destination MAC Address as Any. We're going to specify the Source MAC Address value as 005042 followed by six ones. We'll do the same Source MAC Wildcard Mask, or six zeroes followed by six ones. Click Apply, Close to create our access control entries.
We could add more for any of the game console types that are out there, or any other device that we want to prohibit from using our network.
We can also add anything we want to allow on the network. Now that we've created the MAC Based ACL Table, and have created the entries in that table, we need to make sure that the ports have a binding to that table. We'll go ahead and click on ACL Binding. Select Port One, scroll down, and click Edit. We want to apply this MAC based ACL, so we'll select that and then select Games, which we just created. If there were additional ones, we could choose from them as well. We'll go ahead and click Apply, Close.
Just as we've done in the previous portions of this demonstration, we'll select Port One. The GE One interface, and click on Copy Settings. We'll enter two through 28 and click Apply. That gave us a successful binding of the Games ACL to all of the ports in our interface.
One final thing that you will always want to do when you've made configuration changes to your switch is to save the Running Configuration to the Startup Configuration. On this switch, simply click Save at the top. It will blink when there have been changes. Select Running Configuration as the Source File Name. And set the Destination File Name as Startup Configuration, then click Apply.
In this demonstration we've examined the idea of port security. We've looked at management access to our switch. And we've also looked at restricting certain traffic to the switch using ACLs.

5.9.7 Harden a Switch (Simulation)

Scenario

You are the IT security administrator for a small corporate network. You need to increase the security on the switch in the networking closet.

The following table lists the used and unused ports:

Unused Ports	Used Ports
GE2 GE7 GE9-GE20 GE25 GE27-GE28	GE1 GE3-GE6 GE8 GE21-GE24 GE26

In this lab, your task is to:

- Shut down the unused ports.
- Configure the following Port Security settings for the used ports:
  - Interface Status: **Lock**
  - Learning Mode: **Classic Lock**
  - Action on Violation: **Discard**

Explanation

While completing this lab, use the following information:

Unused Ports	Used Ports
GE2 GE7 GE9-GE20 GE25 GE27-GE28	GE1 GE3-GE6 GE8 GE21-GE24 GE26

Complete this lab as follows:

1. Shut down the unused ports.
   a. Under Initial Setup, select **Configure Port Settings** .
   b. Select the **GE2** port.
   c. Scroll down and select **Edit** .
   d. Under Administrative Status, select **Down** .
   e. Scroll down and select **Apply** .
   f. Select **Close** .
   g. With the GE2 port selected, scroll down and select **Copy Settings** .
   h. In the Copy configuration field, enter the remaining **unused ports** . (View the example for the proper syntax.)
   i. Select **Apply** . From the Port Setting Table, in the Port Status column, you can see that all the ports are down now.

2. Configure the Port Security settings.
    a. From the left menu, expand **Security** .
    b. Select **Port Security** .
    c. Select the **GE1** port.
    d. Scroll down and select **Edit** .
    e. For Interface Status, select **Lock** .
    f. For Learning Mode, make sure **Classic Lock** is selected.
    g. For Action on Violation, make sure **Discard** is selected.
    h. Select **Apply** .
    i. Select **Close** .
    j. Scroll down and select **Copy Settings** .
    k. Enter the remaining **used ports** . (View the example for the proper syntax.)
    l. Select **Apply** .

5.9.8 Secure Access to a Switch (Simulation)

Scenario

You are the IT security administrator for a small corporate network. You need to increase the security on the switch in the Networking Closet by restricting access management.

In this lab, your task is to:

- Create an access profile named *MgtAccess* and configure it with the following settings:

Setting	Value
Access Profile Name	MgtAccess
Rule Priority	1
Management Method	All
Action	Deny
Applies to Interface	All
Applies to Source IP address	All

- Add a profile rule to the *MgtAccess* profile with the following settings:

Setting	Value

Rule Priority	2
Management Method	HTTP
Action	Permit
Applies to interface	All
Applies to Source IP address	User defined IP Version: Version 4 IP Address: 192.168.0.10 Network Mask: 255.255.255.0

- Set the *MgtAccess* profile as the active access profile.
- Save the changes to the switch's startup configuration file using the default settings.

If you need to log back into the switch, the username is **ITSwitchAdmin** , and the password is **Admin$only** .

Explanation

Complete this lab as follows:

1. Create and configure an Access Profile named *MgtAccess* .
    a. From the left pane, expand and select **Security** > **Mgmt Access Method** > **Access Profiles** .
    b. Select **Add** .
    c. Enter the Access Profile Name of **MgtAccess** .
    d. Enter the Rule Priority of **1** .
    e. For Action, select **Deny** .
    f. Select **Apply** and then select **Close** .
2. Add a profile rule to the *MgtAccess* profile.
    a. From the left pane, under **Security** > **Mgmt Access Method** , select **Profile Rules** .
    b. From the right pane, select the **MgtAccess** profile and then select **Add** .
    c. Enter a Rule Priority of **2** .
    d. For Management Method, select **HTTP** .
    e. For *Applies to Source IP Address* , select **User Defined** .
    f. For IP Address, enter **192.168.0.10** .
    g. For Mask, enter a Network Mask of **255.255.255.0** .
    h. Select **Apply** and then select **Close** .
3. Set the MgtAccess profile as the active access profile.
    a. From the left pane, under **Security** > **Mgmt Access Method** , select **Access Profiles** .
    b. Use the Active Access Profile drop-down list to select **MgtAccess** .
    c. Select **Apply** .
    d. Select **OK** .
4. Save the changes to the switch's startup configuration file.
    a. At the top, select **Save** .
    b. On the right, under *Source File Name* , make sure **Running configuration** is selected.
    c. For the Destination File Name, make sure **Startup configuration** is selected.
    d. Select **Apply** .

e. Select **OK** .

5.9.9 Secure Access to a Switch 2 (Simulation)

Scenario

You are the IT security administrator for a small corporate network. You need to increase the security on the switch in the Networking Closet by creating an access control list. You have been asked to prevent video game consoles from connecting to the switch.

In this lab, your task is to:

- Create a MAC-based ACL named **GameConsoles** .
- Configure the **GameConsoles** MAC-based access control entry (ACE) settings as follows:

Priority	Action	Destination MAC Address	Source MAC Address
1	Deny	Any	Value: **00041F111111** Mask: **000000111111**
2	Deny	Any	Value: **005042111111** Mask: **000000111111**
3	Deny	Any	Value: **000D3A111111** Mask: **000000111111**
4	Deny	Any	Value: **001315111111** Mask: **000000111111**
5	Deny	Any	Value: **0009BF111111** Mask: **000000111111**
6	Deny	Any	Value: **00125A111111** Mask: **000000111111**

- Bind the **GameConsoles** ACL to all of the **GE1-GE30** interfaces.

  Use **Copy Settings** to apply the binding to multiple interfaces.

- Save the changes to the switch's startup configuration file. Use the default settings.

Explanation

While completing this lab, use the following information:

- Configure the *GameConsoles* MAC-based access control entry (ACE) settings as follows:
-

Priority	Action	Destination MAC Address	Source MAC Address
1	Deny	Any	Value: **00041F111111** Mask: **000000111111**
2	Deny	Any	Value: **005042111111** Mask: **000000111111**
3	Deny	Any	Value: **000D3A111111** Mask: **000000111111**
4	Deny	Any	Value: **001315111111** Mask: **000000111111**
5	Deny	Any	Value: **0009BF111111** Mask: **000000111111**
6	Deny	Any	Value: **00125A111111** Mask: **000000111111**

Complete this lab as follows:

1. Create the GameConsoles ACL.
    a. From the Getting Started page, under Quick Access, select **Create MAC-Based ACL** .
    b. Select **Add** .
    c. In the *ACL Name* field, enter **GameConsoles** .
    d. Select **Apply** and then select **Close** .
2. Create a MAC-based access control.
    a. Select **MAC-Based ACE** .
    b. Select **Add** .
    c. Enter the ***priority*** .
    d. Select the ***action*** .
    e. For Destination MAC Address, make sure **Any** is selected.
    f. For Source MAC Address, select **User Defined** .
    g. Enter the ***source MAC address value*** .
    h. Enter the ***source MAC address mask*** .
    i. Select **Apply** .
    j. Repeat steps 2c–2i for the remaining ACE entries.
    k. Select **Close** .
3. Bind the GameConsoles ACL to all of the interfaces.
    a. From the left pane, under Access Control, select **ACL Binding (Port)** .
    b. Select **GE1** .
    c. At the bottom of the window, select **Edit** .
    d. Select **Select MAC-Based ACL** .

e. Select **Apply** and then select **Close** .
f. Select **Copy Settings** .
g. In the Copy configuration's *to* field, enter **2-30** .
h. Select **Apply** .

4. Save the Configuration.
    a. From the top of the window, select **Save** .
    b. On the right, under *Source File Name* , make sure **Running configuration** is selected.
    c. Under *Destination File Name* , make sure **Startup configuration** is selected.
    d. Select **Apply** .
    e. Select **OK** .

5.9.10 Practice Questions (Section Quiz)

q_sec_swi_802x_01_secp8

You want to increase the security of your network by allowing only authenticated users to access network devices through a switch.

Which of the following should you implement?

Answers:

- ***802.1x authentication**
- Port security
- Spanning Tree Protocol
- IPsec

Explanation:

802.1x authentication is an authentication method used on a LAN to allow or deny access based on a port or connection to the network. 802.1x is used for port authentication on switches and to wireless access points and requires an authentication server for validating user credentials. This server is typically a RADIUS server. Authenticated users are allowed full access to the network, while unauthenticated users only have access to the RADIUS server.

Port security uses the MAC address to allow or deny connections based on the MAC address of the device, not user authentication.

Spanning Tree is a protocol for identifying multiple paths through a switched network.

IPsec is a tunneling protocol that adds encryption to packets.

q_sec_swi_802x_02_secp8

Which of the following scenarios would typically utilize 802.1x authentication?

Answers:

- ***Controlling access through a switch**
- Controlling access through a router
- Authenticating remote access clients
- Authenticating VPN users through the internet

Explanation:

802.1x authentication is an authentication method used on a LAN to allow or deny access based on a port or connection to the network. 802.1x is used for port authentication on switches and requires an authentication server for validating user credentials. This server is typically a RADIUS server.

Remote access authentication is handled by remote access servers or a combination of remote access servers and a RADIUS server for centralized authentication.

VPN connections can be controlled by remote access servers or by a special device called a VPN concentrator.

q_sec_swi_mac_filtering_secp8

As a network administrator, you have implemented MAC filtering as a security measure on your company's network. You notice that an unauthorized device has been able to connect to the network despite the MAC filtering.

Which of the following is the MOST likely explanation for this occurrence and what should be your next step?

Answers:

- The MAC address of the unauthorized device has been manually added to the allowed list. You should review the allowed list and remove any unfamiliar addresses.
- ***The unauthorized device has spoofed the MAC address of an authorized device. You should implement a secondary authentication method to increase security.**
- The MAC filtering feature is malfunctioning. You should troubleshoot the feature or consider replacing the switch.
- The unauthorized device has bypassed the MAC filtering by connecting to a disabled port. You should ensure all unused ports are properly disabled.

Explanation:

The unauthorized device has spoofed the MAC address of an authorized device is the most likely explanation. You should implement a secondary authentication method to increase security. MAC spoofing is a technique where an unauthorized device mimics the MAC address of an authorized device, thereby bypassing the MAC filtering. To prevent this, a secondary authentication method, such as 802.1x port-based authentication, can be implemented.

The MAC address of the unauthorized device has been manually added to the allowed list could be a possibility if someone with access to the MAC filtering settings has mistakenly or intentionally added the unauthorized device's MAC address to the allowed list. However, this is less likely than option B, as MAC spoofing is a common method used to bypass MAC filtering.

While it's possible that the MAC filtering feature could be malfunctioning, this is less likely than the device spoofing a MAC address. Troubleshooting the feature or replacing the switch should only be considered after other more likely possibilities have been ruled out.

If a port is disabled, it should not allow any device to connect through it, so this is not a likely explanation. However, it's always a good practice to ensure unused ports are properly disabled to prevent unauthorized access.

q_sec_swi_port_sec_01_secp8

In which of the following situations would you use port security?

Answers:

- You want to prevent sniffing attacks on the network.
- ***You want to restrict the devices that could connect through a switch port.**
- You want to control the packets sent and received by a router.
- You want to prevent MAC address spoofing.

Explanation:

Use port security on a switch to restrict the devices that can connect to the switch. Port security uses the MAC address to identify allowed and denied devices. When an incoming frame is received, the switch examines the source MAC address to decide whether to forward or drop the frame.

Port security cannot prevent sniffing or MAC address spoofing attacks.

Use an access control list on a router to control sent and received packets.

q_sec_swi_port_sec_02_secp8

You are the network administrator for a city library. Throughout the library are several groups of computers that provide public access to the internet. Supervision of these computers has been difficult. You've had problems with patrons bringing personal laptops into the library and disconnecting the network cables from the library computers to connect their laptops to the internet.

The library computers are in groups of four. Each group of four computers is connected to a hub that is connected to the library network through an access port on a switch. You want to restrict access to the network so that only library computers are permitted connectivity to the internet.

What can you do?

Answers:

- ***Configure port security on the switch.**
- Remove the hub and place each library computer on its own access port.
- Create a VLAN for each group of four computers.
- Create static MAC addresses for each computer and associate each address with a VLAN.

Explanation:

Configuring port security on the switch can restrict access so that only specific MAC addresses can connect to the configured switch port. This would prevent the laptop computers from being permitted connectivity.

Placing each library computer on its own access port would have no effect.

VLANs are used to group broadcast traffic and do not restrict connectivity of devices as needed in this scenario.

q_sec_swi_spanning_secp8

You manage a single subnet with three switches. They are connected to provide redundant paths between the switches.

Which feature prevents switching loops and ensures there is only a single active path between any two switches?

Answers:

- Trunking
- ***Spanning Tree Protocol**
- PoE
- 802.1x
- Bonding

Explanation:

Spanning Tree Protocol is a protocol on a switch that allows the switch to maintain multiple paths between switches within a subnet. Spanning Tree Protocol runs on each switch and is used to select a single path between any two switches.

- Without Spanning Tree Protocol, switches that are connected together with multiple links would form a switching loop where frames are passed back and forth continuously.
- Spanning Tree Protocol provides only a single active path between switches. Switch ports that are part of that path are placed in a forwarding state.
- Switch ports that are part of redundant but unused paths are placed in a blocking (non-forwarding) state.
- When an active path goes down, Spanning Tree Protocol automatically recovers and activates the backup ports necessary to provide continued connection between devices.

Bonding does the opposite of Spanning Tree Protocol. Bonding allows multiple switch ports to be used at the same time to reach a specific destination.

802.1x is an authentication protocol used with port security (or port authentication).

Power over Ethernet (PoE) supplies power to end devices through the RJ-45 Ethernet switch port.

Trunking identifies ports that are used to carry VLAN traffic between switches. A trunk port is a member of all VLANs defined on all switches.

q_sec_swi_vlan_01_secp8

When configuring VLANs on a switch, which type of switch ports are members of all VLANs defined on the switch?

Answers:

- ***Trunk ports**
- Uplink ports
- Any port not assigned to a VLAN
- Gigabit and higher Ethernet ports
- Each port can only be a member of a single VLAN

Explanation:

A trunk port is a member of all VLANs defined on a switch and carries traffic between the switches. When trunking is used, frames that are sent over a trunk port are tagged by the first switch with the VLAN ID so that the receiving switch knows to which VLAN the frame belongs.

Typically, uplink ports (which are faster than the other switch ports) are used for trunk ports (not VLANs), although any port can be designated as a trunk port.

On an unconfigured switch, ports are members of a default VLAN (often designated VLAN 1). When you remove the VLAN membership of a port, it is reassigned back to the default VLAN. Therefore, the port is always a member of at least one VLAN.

The hardware used (gigabit and higher Ethernet ports) is not a factor in assigning switch port to VLANs.

Once again, by default, the port is always a member of at least one VLAN, but can be a member of several VLANs.

q_sec_swi_vlan_02_secp8

Which of the following BEST describes the concept of a virtual LAN?

Answers:

- Devices connected by a transmission medium other than a cable (microwave, radio transmissions).
- Devices in separate networks (different network addresses) logically grouped as if they were in the same network.
- ***Devices on the same network logically grouped as if they were on separate networks.**
- Devices connected through the internet that can communicate without using a network address.
- Devices on different networks that can receive multicast packets.

Explanation:

A virtual LAN is created by identifying a subset of devices on the same network logically grouped as if they were on separate networks. Think of VLANs as subdivisions of a LAN.

Devices connected by a transmission medium other than a cable normally rely on a Wi-Fi connection, not a VLAN.

The devices on a VLAN need to be on the same network--not separate networks.

The devices on a VLAN need to be assigned a network address in order to communicate with each other.

Once again, devices on a VLAN need to be on the same network, whether they can receive multicast packets or not.

q_sec_swi_vlan_03_secp8

The IT department of a medium-sized enterprise is reviewing its network architecture with a focus on increasing security and efficiency. The organization currently uses a flat network model, but the security team has proposed implementing Virtual Local Area Networks (VLANs) to compartmentalize traffic and minimize potential attack surfaces.

The team's goal is to limit lateral movement between network devices and enforce a principle of least privilege across the network.

Considering this security improvement initiative, what is a major benefit of integrating VLANs into the existing network architecture from a security standpoint?

Answers:

- Enhancing bandwidth efficiency and speed
- ***Isolating network traffic and reducing the potential attack surface**
- Improving scalability by adding more devices to the network
- Providing an alternative for physical cabling and switches

Explanation:

VLANs isolate network traffic and reduce the potential attack surface, enabling the logical segmentation of networks into isolated broadcast domains. As a result, they limit lateral movement and reduce the potential attack surface.

While VLANs can contribute to better network management, the main security benefit does not relate to bandwidth efficiency or speed.

Although VLANs can handle more devices compared to a flat network, the question focuses on the security benefits, not network expansion.

While it is true that VLANs can reduce the need for physical cabling and switches, this is more of a cost and management benefit, not a primary security advantage.

q_sec_swi_vlan_04_secp8

A newly established organization has decided to implement Virtual LANs (VLANs) for segmenting workstation computer hosts from Voice over Internet Protocol (VoIP) handsets.

The organization is using two VLANs that map to two subnets: 10.1.32.0/24 for workstation computers and 10.1.40.0/24 for VoIP handsets.

In this setup, what could be a potential security advantage?

Answers:

- ***Enhanced control over communication between VLANs.**
- Unrestricted communication between devices on different VLANs.
- Immunity from unauthorized communication interception.
- Physical security of network devices and connected computers.

Explanation:

One security advantage of implementing VLANs is the ability to apply access control rules that prevent or permit certain types of communication between VLANs, hence mitigating risks.

One of the main purposes of VLANs is to segment the network, meaning devices from different VLANs cannot freely communicate with each other without routing.

While VLANs can increase network security by segregating traffic, they do not make it impossible for unauthorized individuals to intercept communications. The organization would need other security measures, like encryption, for that purpose.

While VLANs contribute to network security, they do not ensure the physical security of network devices and connected computers. The organization would require physical security measures for that purpose.

q_sec_swi_vlan_05_secp8

A network engineer is segmenting a company's network to improve security. In terms of routing infrastructure, which of the following strategies would the engineer employ to segment different types of hosts attached to the same switch?

Answers:

- ***Assign each host to a different virtual local area network (VLAN).**
- Assign a different internet protocol (IP) address to each host on the switch.

- Use the Address Resolution Protocol (ARP) to map each host's IP interface to a different media access control (MAC) address.
- Use the same VLAN IDs and subnets for all hosts.

Explanation:

The network engineer can create separate broadcast domains by assigning each host to a different VLAN. The engineer should route traffic sent from one VLAN to another, providing an additional layer of security and segmentation.

Even though the network engineer assigns a unique IP address to each host, it does not necessarily provide segmentation at the level of the switch.

Although the network engineer uses ARP to map IP interfaces to MAC addresses, it does not serve as a strategy for network segmentation.

The network engineer does not create segmentation within the switch using the same VLAN IDs and subnets for all hosts. The engineer should assign different hosts to different VLANs for effective segmentation.

q_sec_swi_vlan_switches_secp8

As a network administrator, you are tasked with creating VLANs on a switch to improve network performance and security.

You decide to create VLANs based on different departments in your company. However, you notice that devices from different VLANs are unable to communicate with each other.

Which of the following is the MOST likely reason for this and what should be your next step?

Answers:

- The switch is not properly configured for VLANs. You should review the VLAN configuration on the switch.
- The devices are not properly configured for VLANs. You should review the network settings on each device.
- ***Inter-VLAN routing is not enabled. You should implement a router or a Layer 3 switch to enable communication between VLANs.**
- The switch ports are not correctly assigned to the VLANs. You should review the VLAN assignments for each port.

Explanation:

Inter-VLAN routing is not enabled is is the most likely explanation. By default, devices in different VLANs cannot communicate with each other. To enable communication between VLANs, you need to implement a router or a Layer 3 switch for inter-VLAN routing.

The switch is not properly configured for VLANs could be a possibility if the switch is not correctly configured for VLANs. However, if the devices are correctly assigned to their respective VLANs and are able to communicate within their VLAN, it's likely that the switch is correctly configured for VLANs.

The devices do not need to be specifically configured for VLANs. The switch handles the VLAN assignments based on the switch ports, so this is not a likely explanation.

If the switch ports were not correctly assigned to the VLANs, the devices would not be able to communicate even within their VLAN. Since the devices are able to communicate within their VLAN, it's likely that the switch ports are correctly assigned to the VLANs.

q_swi_attack_arp_poison_secp8

Which of the following switch attacks associates the attacker's MAC address with the IP address of the victim's devices?

Answers:

- MAC spoofing
- ***ARP spoofing/poisoning**
- DNS poisoning
- Cross-site scripting (XSS)

Explanation:

ARP spoofing/poisoning associates the attacker's MAC address with the IP address of the victim.

MAC spoofing is changing the source MAC address on frames sent by the attacker.

DNS poisoning occurs when a name server receives malicious or misleading data that incorrectly maps host names and IP addresses.

Cross-site scripting (XSS) attacks are a type of injection attack where malicious code is saved onto an otherwise benign site.

q_swi_attack_harden_switches_secp8

You are a network security analyst for a large corporation. The company has recently experienced a series of network attacks, and you've been tasked with hardening the network switches to prevent future attacks. You've identified several potential measures to improve security.

Which of the following would be the MOST effective approach to hardening the switches?

Answers:

- Changing the default credentials.
- Implementing Access Control Lists (ACLs).
- Enabling HTTP services for remote management.
- ***Disabling unnecessary services and interfaces.**

Explanation:

Disabling unnecessary services and interfaces is the most effective approach. Disabling unnecessary services and interfaces reduces the attack surface of the switch, making it harder for attackers to gain access. This is a more comprehensive measure compared to the other options, making it the most effective approach to switch hardening.

Changing default credentials is a basic step in hardening any device, as default credentials are often well-known and pose a significant security risk. However, this measure alone does not provide a comprehensive approach to switch hardening.

ACLs restrict access to the switch, providing a layer of security. However, this measure alone does not provide a comprehensive approach to switch hardening.

Enabling HTTP services for remote management can actually introduce security vulnerabilities, as HTTP is not a secure protocol. This would not be an effective approach to hardening the switches and is therefore not the most effective approach.

q_swi_attack_l2_attack_secp8

Drag each description on the left to the appropriate switch attack type on the right.

Answers:

- Causes packets to fill up the forwarding table and consumes so much of the switch's memory that it enters a state called Fail Open Mode.
- The source device sends frames to the attacker's MAC address instead of to the correct device.
- Can be used to hide the identity of the attacker's computer or impersonate another device on the network.
- Should be disabled on the switch's end user (access) ports before implementing the switch configuration into the network.

Explanation:

Common attacks that are perpetrated against switches are MAC flooding, ARP spoofing/poisoning, and MAC spoofing.

MAC flooding overloads the switch's MAC forwarding table to make the switch function like a hub.

- The attacker floods the switch with packets, each containing a different source MAC address.
- The flood of packets fills up the forwarding table and consumes so much of the memory in the switch that it causes the switch to enter into fail open mode. While in this mode, all incoming packets are broadcast out of all ports (as with a hub) instead of just to the correct ports, as per normal operation.
- The attacker captures all the traffic with a protocol analyzer/sniffer.

ARP spoofing/poisoning associates the attacker's MAC address with the IP address of victim devices.

- When computers send an ARP request for the MAC address of a known IP address, the attacker's system responds with its own MAC address.
- The source device sends frames to the attacker's MAC address instead of to the correct device.
- Switches are indirectly involved in the attack because they do not verify the MAC address/IP address association.

MAC spoofing changes the source MAC address on frames sent by the attacker.

- MAC spoofing is typically used to bypass 802.1x port-based security.
- MAC spoofing can be used to bypass wireless MAC filtering.
- MAC spoofing can be used to hide the identity of the attacker's computer or to impersonate another device on the network.

Dynamic Trunking Protocol (DTP) switches have the ability to automatically detect trunk ports and negotiate the trunking protocol used between devices. DTP is not secure and allows unauthorized devices to possibly modify configuration information. You should disable the DTP services on the switch's end user (access) ports before implementing the switch configuration into the network.

q_swi_attack_mac_flood_secp8

Which of the following attacks, if successful, causes a switch to function like a hub?

Answers:

- ARP poisoning

- ***MAC flooding**
- MAC spoofing
- Replay attack

Explanation:

MAC flooding overloads the switch's MAC forwarding table to make the switch function like a hub. The attacker floods the switch with packets, each containing different source MAC addresses. The flood of packets fills up the forwarding table and consumes so much of the memory in the switch that it causes the switch to enter a state called fail open mode. While in this mode, all incoming packets are broadcast out of all ports (as with a hub), instead of just to the correct ports, as per normal operation.

ARP poisoning associates the attacker's MAC address with the IP address of victim devices. When computers send an ARP request to get the MAC address of a known IP address, the attacker's system responds with its own MAC address. MAC spoofing is changing the source MAC address on frames sent by the attacker.

In a replay attack, the attacker uses a protocol analyzer or sniffer to capture authentication information going from the client to the server. The attacker then uses this information to connect at a later time and pretend to be the client.

q_swi_attack_mac_spoof_secp8

Which of the following is a typical goal of MAC spoofing?

Answers:

- ***Bypass 802.1x port-based security**
- Cause a switch to enter fail open mode
- Cause incoming packets to broadcast to all ports
- Reroute local switch traffic to a specified destination

Explanation:

MAC spoofing is changing the source MAC address on frames sent by the attacker. It is typically used to bypass 802.1x port-based security, to bypass wireless MAC filtering or hide the identity of the attacker's computer.

MAC flooding causes a switch to enter fail open mode, which causes incoming packets to be broadcast out to all ports. ARP spoofing/poisoning associates the attacker's MAC address with the IP address of the victim.

q_swi_attack_port_sec_secp8

Which protocol should you disable on the user access ports of a switch?

Answers:

- TCP
- ***DTP**
- PPTP
- IPsec

Explanation:

Switches have the ability to automatically detect ports that are trunk ports and to negotiate the trunking protocol used between devices. DTP is not secure and allows unauthorized devices to possibly modify configuration information. You should disable DTP services on the switch's end user (access) ports.

Transmission Control Protocol (TCP) is a communications standard that enables application programs and computing devices to exchange messages over a network and is important for traffic passing through a switch.

Point-to-Point Tunneling Protocol (PPTP) is a network protocol that enables the secure transfer of data from a remote client to a private enterprise server by creating a virtual private network (VPN) across TCP/IP-based data networks. PPTP can be important for the security of traffic passing through a switch.

IPSec is a set of communication rules or protocols for setting up secure connections over a network. Internet Protocol (IP) is the common standard that determines how data travels over the internet. IPSec adds encryption and authentication to make the protocol more secure, and can be important to for the security of traffic passing through a switch.

q_swi_attack_udp_secp8

You are a network security analyst for a large corporation. The company is planning to launch a new real-time video streaming service for its employees.

You've been tasked with selecting the most suitable transport protocol to ensure the best performance for this service.

Which of the following protocols would be the MOST effective for this purpose?

Answers:

- Transmission Control Protocol (TCP)
- ***User Datagram Protocol (UDP)**
- Secure Shell (SSH)
- Hypertext Transfer Protocol Secure (HTTPS)

Explanation:

User Datagram Protocol (UDP) is the correct answer. UDP is a connectionless protocol, making it faster than TCP and more suitable for real-time applications like video streaming, telephony, and gaming, where occasional packet loss is less impactful than latency. Therefore, UDP is the most effective choice for a real-time video streaming service.

Transmission Control Protocol (TCP) is a connection-oriented protocol that provides reliability, ordering, and error-checking. While it is suitable for applications requiring high levels of reliability, it is not the best choice for real-time applications like video streaming where occasional packet loss is less impactful than latency.

Secure Shell (SSH) is a cryptographic network protocol for operating network services securely over an unsecured network. While it provides secure data communication, it is not specifically designed for real-time applications like video streaming.

Hypertext Transfer Protocol Secure (HTTPS) is a secure version of HTTP, used primarily for secure communication over a computer network. While it provides secure communication, it is not specifically designed for real-time applications like video streaming.

5.10 Router Security

As you study this section, answer the following questions:

- Why should you change the default settings on new routers?
- Which secure protocols should you use to remotely manage a router?
- What actions can you take to ensure the physical security of network devices?
- Why should you update router firmware?
- How do ACLs work on a router?

In this section, you will learn to:

- Configure ACLs.
- Restrict Telnet and SSH access.
- Permit traffic.
- Block source hosts.

The key terms for this section include:

Term	Definition
Router	A network device that transmits data from one network to another.
Access control list (ACL)	A list of permissions associated with a network object, such as a router or a switch, that controls traffic at a network interface level.

This section helps you prepare for the following certification exam objectives:

Exam	Objective

CompTIA Security+ SY0-701	2.3 Explain various types of vulnerabilities.
	• Hardware
	  ○ Firmware
	
	2.5 Explain the purpose of mitigation techniques used to secure the enterprise.
	• Access control
	  ○ Access control list (ACL)
	  ○ Permissions
	• Hardening techniques
	  ○ Disabling ports/protocols
	  ○ Default password changes
	
	3.2 Given a scenario, apply security principles to secure enterprise infrastructure.
	• Secure communication/access
	  ○ Remote access
	
	4.1 Given a scenario, apply common security techniques to computing resources.

	• Hardening targets
	  ○ Routers
	
	4.5 Given a scenario, modify enterprise capabilities to enhance security.
	
	• Implementation of secure protocols
	  ○ Protocol selection
	
	5.1 Summarize elements of effective security governance.

TestOut Security Pro	2.2 Harden Network Devices 2.2.5 Configure Router Security

5.10.1 Router Security (Lesson Video)

Transcript:

We're going to talk about using a secure router configuration. If you're responsible for managing routers, it is critical that you use a secure router configuration. The way you do this depends on router manufacturer, model, configuration interface, and other factors.

In this lesson, we're going to look at some general router security principles that apply to a wide variety of router makes and models.
The most important aspect of securing any router, regardless of manufacturer, is changing default configuration settings. By default, routers are configured to use a predetermined username and password. Typically, this is something like admin and admin, or admin and password, or something very similar. There's actually even lists out on the internet that have the default username and password for practically every router model.
Because of this, it's extremely important you immediately change the default username and password on a router. In fact, I would recommend you changing this configuration before you even connect the router to the rest of the network or internet. This will ensure that there is zero chance someone will compromise the router before you have a chance to change this configuration.
When you're changing the default username, make sure to name it something other than admin or administrator or root or something easily guess. Also make sure you use a very complex password that includes numbers, symbols, upper- and lower-case letters, and is at minimum 12 characters long.
Another default setting you might consider changing is the default network address. Depending on how your organization is configured, you might have the ability to select a different IP address range than the default 192.168.1 network address that most routers use. This approach is known as security through obscurity, which by itself isn't actually secure, but if layered with other security techniques, it can add just one more obstacle an attacker has to get through, albeit a small one.
Depending on the device or organization you work for, you might be using a SOHO all-in-one router that includes switching and Wi-Fi capabilities. If this is the case, make sure to change the default SSID name and wireless encryption settings.
Another thing you should do when you first set up a router is make sure the firmware is up-to-date. Oftentimes routers are shipped with older firmware versions. Firmware updates contain much needed security fixes and vulnerability fixes, so it's important you are using the latest firmware version available. And always make sure you keep the router updated with the latest firmware.
The next configuration changes you want to make is that of the protocol used to connect to the router.

Some routers use connection protocols that send authentication credentials in cleartext. This makes it very easy for someone to capture packets and identify the login information for the device. While most modern routers will use some type of secure protocol, such as SSL, it's possible you might work with an older router that uses an older, unencrypted protocol by default. If this is the case, be aware that you should use a secure protocol.
For example, some routers might have FTP functionality that allows you to upload configuration files or firmware updates to the router. Because FTP is an unencrypted transmission protocol, the configuration file could be easily captured. Instead, you might be able to use SFTP, which is the secure, encrypted form of FTP.
Now, this does all depend on how you are connecting to the router to configure it. Some routers have a dedicated serial port that is used to configure the router. This is done instead of a remote configuration portal using a web browser or SSH. If this is the case, you might not need to worry about encrypted transmissions. However, if you are working with the router remotely, be sure you know which transmission protocol is being used and whether or not it is secure.
Speaking of using secure protocols, there's one protocol that I want to quickly talk about that some routers use, especially SOHO routers. That protocol is universal plug and play (UPnP).
UPnP was designed to make setting up media and IoT devices, such as smart TVs and gaming consoles, a breeze. It works by opening up ports for devices inside the network on the fly, eliminating the need to manually open up ports for these devices. In theory, it's a nice idea. However, in practice? Not so much.
UPnP has been plagued with exploit after exploit since it was implemented. These exploits range from annoying to downright scary. Because of this, I highly recommend simply disabling UPnP on any router that has it. At this time, the convenience isn't worth the risk.
Another area you need to look at with routers is that of remote access.
Most routers will allow you to configure remote access optionsâ€”both remote access from within the network and remote access from outside the network via the internet.
It might not be possible to disable remote access from inside the network. For example, the router might be locked inside of a networking closet or server rack case and accessing the router would require you to be inside the frigid server room. If this is the case, make sure the login credentials for remote access are configured properly and the protocol used is secure.
Remote access from outside, on the other hand, should 99% of the time be disabled. There are really only a handful of times remote access from outside the network would be necessary. And for these occasions, I recommend only enabling for as long as you need it, and not a moment longer. Allowing remote access from outside the network opens up entire attack surface that you shouldn't have to worry about.
Like I said earlier, you might not be able to have physical access to the router all the time, and this is actually a good thing.
As you already know, it's always a good idea to keep networking devices and critical infrastructure components under lock and key, and routers are no different. With physical access, it's possible for an attacker to access a router even if they don't have the proper login credentials. Because of this, make sure routers are stored in a secure location. At the very least, keep the router in a locked cabinet. But keeping it with other networking equipment in a locked cage or lock server room that has the appropriate physical security controls is best.
Another important aspect of proper router security is that of the configuration file.
The configuration file stores all the configure settings for the router, including open ports, usernames, firewall settings, et cetera. And often times these files can be backed up remotely on a USB drive or workstation. If you do backup these files, be sure to properly encrypt them so they can't easily read.
In addition, a lot of routers offer the option to encrypt the configuration file on the device itself. If your router happens to have this option, enable it. This provides an additional layer of security should someone gain access to this file.
And speaking of backing up the configuration file, do so on a regular basis. And as I said earlier, secure you backups by encrypting them.
Your network is only as strong as its weakest link. And if that weak link is the primary entry point into your network, as the router is, you might have a lot of problems on your hands. Keep this in mind when securing your network and take the extra time and steps we discussed in this lesson to properly secure your router.

5.10.2 Router ACLs (Lesson Video)

Transcript:

Like a firewall, a router can use access control lists (ACLs) to protect a network from attacks and control what type of communications are allowed on the network.

Don't confuse the ACL on a router with its routing table. The routing table is used to determine where network packets are forwarded to. The ACL, on the other hand, is used to determine whether or not a packet is allowed to be forwarded. For example, an ACL on a router could ban all incoming traffic destined to a specific IP address inside the network. Any packet destined for that IP address is dropped. However, outgoing packets from that IP address are still permitted.
When you create an ACL on a router, it almost always includes a hidden deny any statement at the end of the list. This means all traffic is automatically blocked. To allow traffic, you need at least one permit statement that either permits a specific traffic type or permits all traffic not specifically restricted.
The type of traffic you are able to control with an ACL depends on the type of ACL you create. Routers primarily use two ACL types: standard ACLs and extended ACLs.
A standard ACL is only able to filter traffic based on the source host name or host IP address--that is, it can't filter traffic based on port number, destination host name, or host IP address.
For example, you could configure a standard ACL to only allow traffic coming from internal IP addresses. All traffic coming from external IP address would be dropped. You could also configure a standard ACL to block all traffic from a specific IP address, but allow all other traffic. Know that because of how they function, standard ACLs should be placed as close to the destination as possible.
So, what if you wanted to block traffic based on other parameters, such as port number? To do this, you use the second type of ACLâ€""an extended ACL.
Extended ACLs are used to filter traffic based on a lot more parameters than standard ACLs. In addition to filtering based on source host name or host IP address, an extended ACL can filter based on source IP protocol, source or destination socket number, and destination host name or host IP address.
For example, you could block all outgoing traffic except for traffic on ports 80 and 443, or you could block all traffic from inside the network that's destined for a specific IP address.
Unlike standard ACLs, extended ACLs should be placed as close to the source as possible.
That's it for this lesson. In this lesson, we looked at router ACLs. We looked at how ACLs on a router work and what parameters are defined when they are created. We then looked at the two types of ACLs routers use, standard ACLs and extended ACLs.

5.10.3 Router Security Facts

5.10.4 Configuring ACLs (Demo Video)

Transcript:

In this demonstration, we'll show you how to configure access control lists on a Cisco router using the command line interface. Access control lists can give us granular control over how data flows across our networks, and which computers can communicate with specific protocols.

An access control list is simply a sequential list of statements of what can and cannot be done on the network. Those that can be done use the permit keyword. Those that can't be done use the deny keyword.
The ordering of the lines is important. These lists should go from the most specific conditions to the most general.
For instance, if we wanted to disallow FTP on our network, we could create a statement added to our access list that denied FTP. We would do that first, and then later we might allow all other application protocols that sit on top of the IP protocol.
And so, we might have two rules there. It's also important to recognize that there's an implicit deny anything else or any other traffic. This is located at the end of every access control list. In other words, anything that isn't explicitly permitted is implicitly denied.
For our demonstration, we're going to use this Windows 10 virtual machine that you can see over here. You can see that it currently has access to the Internet. We could look up access control lists and find out some information.
We can also see that we can currently ping, say, Google's DNS servers. We have access to the Internet. Let's go ahead and prohibit, or deny access for this computer to the Internet.
I'm going to attach to my Cisco router using Tera Term here. I have a cable going to the console port on the router. You can see that my router is currently, already configured to allow NAT, and it also has some specific configuration settings allowing different networks to connect with each other.
If we wanted to deny access to the Internet for this device, we need to know what its IP address is. We can get that by typing IPconfig here. You can see this is 10.0.0.2.

You can see that it must be connected to this 10.0.0.1 network that's associated with interface FA0/1. To deny a specific host, it's fairly straightforward. We need to get into configuration mode.
Now, you might have read, or you might know that there are two different types of access control lists, with Cisco. There are standard lists, and there are extended ACL. Standard lists only act on the source IP address for filtering.
You can only deny or permit specific hosts based on IP address, not protocols. Whereas, extended access control lists allow you to get pretty granular with which ports are allowed and denied, which protocols are allowed or denied also.
In our case, standard control list will work fine for this action. Now that we're in configuration mode, we're going to create an access list, and we'll just call it access list 10. Standard lists range typically from 1 to 99, or from 1300 to 1999. We'll just choose 10 because that says this is a standard access list.
And then, we will state that we want to deny 10.0.0.2, and specifically just that host. This second parameter is a wild card mask. Essentially, anything that's a zero there, says it has to match, or the IP address has to match that.
In this case, we're only applying this rule to 10.0.0.2. Everything has to match that.
We'll do that. Now, we still have access to the Internet. We can go ahead and refresh. You can see that we still get results. We can't just create the access list. We now need to apply that access list.
And so, in order to apply it, we basically tell it which interface this applies to. We're already in configuration mode, so we'll go to FA0/1, and we'll apply this access list to that.
We're going to apply access list 10 to this interface, and we're going to examine packets as they arrive at this interface on the router. We'll go ahead and say, "Enter there."
And now, if we come over here, we should see that we no longer have access to the Internet. It just kind of spins there. If we come up, and we try to ping, it's unreachable.
Now, one problem with this list is we explicitly denied this host. We've achieved what we wanted to. However, because there's that implicit deny at the end, we've denied access to everything else as well, everything that's coming through FA0/1.
If we wanted to keep that there, we'd want to, maybe create a rule that said access list 10 permit, and then the range of IP addresses that would be permitted.
In this case, let's just go ahead and just disable that access control list. We're still on that, so I'm going to simply type, no IP access group 10 in, which basically reverses the command that I had just done.
We should see that now we have access back out to the Internet. We can refresh this one, as well.
What if we wanted to deny ping, which uses ICMP, while still allowing Internet access? How can we get a little bit more granular? Well, we're going to need extended control lists in order to do that.
Let's go ahead and create an extended access control list. We'll get out of this interface. Let's go ahead and create access list 100. For this one, let's first deny ICMP, and we can specify a single host by just saying, "Host."
We'll say, "Deny this specific host for ICMP." And, to what network? We'll say, "To anything that comes through." The 0.0.0 says, "Anything." Coupled with this wildcard mask then that denies all ICMP.
Now, we haven't applied this list yet, so it still will allow us out to the Internet. We also want to permit access to other types of protocols, or any other protocol besides ICMP. Our second rule on our list will allow us to do that.
We're going to permit IP for that host. We can shorten it and just say, "To any," if we wanted to. Or, maybe we could be a little broader and say, "We're actually going to allow anyone on the 10 dot network to have access to any network."
Let's go ahead and try to apply that to FA0/1. Let's go ahead and try it. So, we are not able to ping, but we are able to get out to the Internet. Let's go ahead and show you that, and that it's not just cached. You can do different queries.
Access control lists are very powerful but can become complicated. It's important that you understand the basics that essentially these are just a sequential list of permit-and-deny statements, with an implicit deny at the end.
Standard access control lists allow you to filter based on a source IP address. Extended access control lists allow you to filter more granularly on specific protocols, or even specific ports for individual hosts, or for whole ranges of addresses.
Okay. That's it for this demonstration. In this demonstration, we showed you how to configure access control lists on a Cisco router using the command line interface.
Access control lists are foundational to allow us to screen the data that comes through our networks that we either allow out or into our corporate networks.

5.10.5 Restrict Telnet and SSH Access (Simulation)

Scenario

You are in the process of configuring a new router. The router interfaces connect to the following networks:

Interface	Network
FastEthernet0/0	192.168.1.0/24
FastEthernet0/1	192.168.2.0/24
FastEthernet0/1/0	192.168.3.0/24

Only Telnet and SSH access from these three networks should be allowed.

In this lab, your task is to:

- Use the **access-list** command to create a standard numbered access list using number 5.
- Add a **permit** statement for each network to the access list.
- Use the **access-class** command to apply the access list to VTY lines 0–4. Use the **in** direction to filter incoming traffic.
- Save your changes in the **startup-config** file.

Explanation

Complete this lab as follows:

1. Enter the configuration mode for the router:
    a. From the exhibit, select the router.
    b. From the terminal, press **Enter** .
    c. Type **enable** and then press **Enter** .
    d. Type **config term** and then press **Enter** .
2. From the terminal, create a standard numbered access list using number 5. Add a **permit** statement for each network to the access list.
    a. Type **access-list 5 permit 192.168.1.0 0.0.0.255** and then press **Enter** .
    b. Type **access-list 5 permit 192.168.2.0 0.0.0.255** and then press **Enter** .
    c. Type **access-list 5 permit 192.168.3.0 0.0.0.25** 5 and then press **Enter** .
3. Apply the access list to VTY lines 0–4. Filter incoming traffic.
    a. Type **line vty 0 4** and then press **Enter** .
    b. Type **access-class 5 in** and then press **Enter** .
    c. Press **Ctrl** + **Z** .
4. Save your changes in the **startup-config** file.
    a. Type **copy run start** and then press **Enter** .
    b. Press **Enter** to begin building the configuration.
    c. Press **Enter** .

5.10.6 Permit Traffic (Simulation)

Scenario

The Fiji router has been configured with Standard IP Access List 11. The access list is applied to the *Fa0/0 interface* . The access list must allow all traffic except traffic coming from hosts 192.168.1.10 and 192.168.1.12. However, you've noticed that it's preventing all traffic from being sent on Fa0/0. You remember that access lists contain an implied **deny any** statement. This means that any traffic not permitted by the list is denied. For this reason, access lists should contain at least one permit statement, or all traffic is blocked.

In this lab, your task is to:

- Add a **permit any** statement to Access List 11 to allow all traffic other than the restricted traffic.
- Save your changes in the **startup-config** file.

Explanation

Complete this lab as follows:

1. Enter the configuration mode for the Fiji router:
    a. From the exhibit, select the *Fiji router* .
    b. From the terminal, press **Enter** .
    c. Type **enable** and then press **Enter** .
    d. Type **config term** and then press **Enter** .
2. From the terminal, add a **permit any** statement to Access List 11 to allow all traffic other than the restricted traffic.
    a. Type **access-list 11 permit any** and press **Enter** .
    b. Press **Ctrl** + **Z** .
3. Save your changes in the **startup-config** file.
    a. Type **copy run start** and then press **Enter** .
    b. Press **Enter** to begin building the configuration.
    c. Press **Enter** .

5.10.7 Block Source Hosts (Simulation)

Scenario

You have a small business network connected to the internet through a single router as shown in the network diagram. You have noticed that three hosts on the internet have been flooding your router with unwanted traffic. As a temporary measure, you want to prevent all communication from these three hosts until the issue is resolved.

In this lab, your task is to:

- Create a Standard Access List 25.
- Add statements to the access list to block traffic from the following hosts:
    - **199.68.111.199**
    - **202.177.9.1**
    - **211.55.67.11**
- Add a statement to allow all other traffic from all other hosts.
- Apply Access List 25 to the *Serial0/0/0 interface* to filter incoming traffic.

You can also use **199.68.111.199 0.0.0.0** (without the **host** parameter) to identify a specific host. You can also use **0.0.0.0 255.255.255.255** to identify any host. Because this is a temporary solution, you do not need to save your changes.

Explanation

Complete this lab as follows:

1. Enter the configuration mode for the router:
    a. From the exhibit, select the router.
    b. From the terminal, press **Enter** .
    c. Type **enable** and then press **Enter** .

d. Type **config term** and then press **Enter** .

2. From the terminal, create a standard numbered access list using number 25. Add statements to the access list to block traffic to the required hosts.
    a. Type **access-list 25 deny host 199.68.111.199** and press **Enter** .
    b. Type **access-list 25 deny host 202.177.9.1** and press **Enter** .
    c. Type **access-list 25 deny host 211.55.67.11** and press **Enter** .
3. From the terminal, add a statement to allow all other traffic from all other hosts, by typing **access-list 25 permit any** and pressing **Enter** .
4. From the terminal, apply Access List 25 to the *Serial0/0/0 interface* to filter incoming traffic.
    a. Type **int s0/0/0** and press **Enter** .
    b. Type **ip access-group 25 in** and press **Enter** .
    c. Type **Ctrl** + **Z** .

5.10.8 Practice Questions (Section Quiz)

q_router_sec_acl_secp8

Which of the following should be configured on the router to filter traffic at the router level?

Answers:

- ***Access control list**
- Anti-spoofing rules
- SSH
- Telnet

Explanation:

Router access control lists (ACLs) can be configured to increase security and limit traffic, much like a firewall but on the router level. ACLs filter the traffic and determine if the data should be blocked or forwarded.

Anti-spoofing rules counter spoofing attacks where IP packets have a source address that does not belong to the sender.

Secure Shell (SSH) is a secure protocol that can be used to connect to the router.

Telnet is an older protocol used to connect to remote devices. It should not be used any longer.

q_router_sec_anti_spoofing_secp8

You are a network security engineer at a large corporation. You have been tasked with implementing anti-spoofing rules on the company's routers to enhance network security.

You have noticed an increase in spoofing attacks where IP packets have a source address that does not belong to the sender.

Which of the following anti-spoofing rule configurations would be the MOST effective in mitigating these attacks?

Answers:

- Source: Any, Destination: Any, Service: Any, Interface: Any external interface, Direction: Inbound, Action: Deny, Time: Any

- ***Source: An IP address belonging to the internal network or the IP address of the router itself, Destination: Any, Service: Any, Interface: Any external interface, Direction: Inbound, Action: Deny, Time: Any**
- Source: An IP address belonging to the external network, Destination: Any, Service: Any, Interface: Any internal interface, Direction: Outbound, Action: Deny, Time: Any
- Source: Any, Destination: An IP address belonging to the internal network or the IP address of the router itself, Service: Any, Interface: Any external interface, Direction: Outbound, Action: Deny, Time: Any

Explanation:

The correct answer is: Source: An IP address belonging to the internal network or the IP address of the router itself, Destination: Any, Service: Any, Interface: Any external interface, Direction: Inbound, Action: Deny, Time: Any. This configuration would effectively block any inbound packets that are pretending to be from the internal network or the router itself, which is a common tactic in spoofing attacks.

Source: Any, Destination: Any, Service: Any, Interface: Any external interface, Direction: Inbound, Action: Deny, Time: Any would block all inbound traffic, regardless of the source, which is not a practical solution as it would disrupt normal network operations.

Source: An IP address belonging to the external network, Destination: Any, Service: Any, Interface: Any internal interface, Direction: Outbound, Action: Deny, Time: Any would block all outbound traffic from any external IP address, which is not a practical solution as it would disrupt normal network operations and does not directly address the issue of spoofing attacks.

Source: Any, Destination: An IP address belonging to the internal network or the IP address of the router itself, Service: Any, Interface: Any external interface, Direction: Outbound, Action: Deny, Time: Any would block all outbound traffic destined for the internal network or the router itself, regardless of the source. While this might prevent some types of attacks, it does not specifically target spoofing attacks where the source address is falsified.

q_router_sec_blocked_secp8

Which of the following happens by default when you create and apply a new ACL on a router?

Answers:

- All traffic is permitted.
- ***All traffic is blocked.**
- The ACL is ignored until applied.
- ACLs are not created on a router.

Explanation:

When first created and applied on a router, an ACL almost always includes a hidden Deny Any statement at the end of the list. This means all traffic is automatically blocked.

All traffic is not permitted by default with a new ACL.

The ACL is immediately applied and blocks all traffic until configured.

ACLs are created on the router itself.

q_router_sec_firmware_secp8

You are deploying a brand new router. After you change the factory default settings, what should you do next?

Answers:

- Secure the configuration file.
- ***Update the firmware.**
- Configure SSH to access the router configuration.
- Configure anti-spoofing rules.

Explanation:

After changing the default settings on the router, you should update the firmware. Updates to the firmware fix any vulnerabilities that have been resolved by the manufacturer in the past.

After updating the firmware, you should configure the protocol used to connect to the router.

The configuration file stores all the configuration settings for the router, including open ports, usernames, firewall settings, and more. If possible, store the router configuration file in an encrypted form and back up the file to a secure location.

Anti-spoofing rules counter spoofing attacks where IP packets have a source address that does not belong to the sender. This is configured after the router is set up.

q_router_sec_locks_secp8

Which of the following can make passwords useless on a router?

Answers:

- ***Not controlling physical access to the router**
- Using the MD5 hashing algorithm to encrypt the password
- Storing the router configuration file in a secure location
- Using SSH to remotely connect to a router

Explanation:

If someone can gain access to the physical device, they can easily bypass any configured passwords. Passwords are useless if physical access is not controlled.

Other security measures you can use include:

- Use the MD5 hashing algorithm to encrypt the password.
- Store the router configuration file in encrypted form to a secure location.
- Use SSH when you remotely connect to a router.

q_router_sec_segmentation_01_secp8

A financial institution is processing transactions and wishes to improve its security posture. The institution divides its network into different sections to minimize risk while actively updating or retrieving transaction data.

What method does the financial institution intend to use?

Answers:

- ***Segmentation**

- Firewalling
- Network address translation (NAT)
- Virtual private network (VPN)

Explanation:

Segmentation works by dividing a network into different sections so that the institution can protect its data while processing.

Firewalling provides a line of defense against attacks but does not involve dividing the network into different sections.

NAT is a method of remapping one Internet Protocol (IP) address space into another by modifying network address information in the IP header of packets. However, it does not provide a method of dividing a network into segments.

A VPN can provide secure remote access to an organization's network, although it does not involve segmenting the network.

q_router_sec_segmentation_02_secp8

A critical infrastructure organization responsible for managing energy distribution across a large region relies heavily on industrial control systems (ICS) and supervisory control and data acquisition (SCADA) systems to monitor and control the power grid.

Given the critical nature of the operations, the IT team has implemented a unique control to safeguard these systems.

Which unique control did the IT team use to protect ICS and SCADA systems?

Answers:

- Regular system updates
- ***Network segmentation**
- Secure boot mechanisms
- Transport encryption protocols

Explanation:

Network segmentation isolates industrial control systems and supervisory control and data acquisition systems from the wider network, protecting them by limiting access and defending against inbound attacks.

Overall security benefits from regular system updates, but they are not unique controls designed to protect ICS/SCADA systems.

Secure boot mechanisms are focused on individual devices such as workstations and servers, not systems such as ICS and SCADA.

Transport encryption protocols are designed to secure the transmission of data, but are not as effective as network segmentation for isolating and protecting systems such as ICS and SCADA systems.

q_router_sec_segmentation_03_secp8

Upon reviewing the results of an organizational assessment, the cyber team implements various remediation practices to safeguard the company's data.

What remediation practices include the division of a network into separate pieces to contain an attack or attempted breach within one piece of the network?

Answers:

- ***Segmentation**
- Compensating controls
- Patching
- Insurance

Explanation:

In this instance, segmentation involves dividing a network into separate pieces to contain potential security breaches.

Not relevant here, compensating controls refer to measures put in place to mitigate the risk of a vulnerability when security teams cannot directly eliminate it or when direct remediation is not immediately possible.

Additionally, patching is one of the most straightforward and effective remediation practices. It involves applying updates and patches to software or systems to fix known vulnerabilities.

Insurance provides financial protection in case of a security breach resulting from a vulnerability and is important in a comprehensive risk management strategy, complementing technical controls with financial risk transfer.

q_router_sec_ssh_01_secp8

You've just deployed a new Cisco router that connects several network segments in your organization.

The router is physically located in a server room that requires an ID for access. You've backed up the router configuration to a remote location in an encrypted file. You access the router configuration interface from your notebook computer using a Telnet client with a username of admin and a password of P@ssW0rd. You have used the MD5 hashing algorithm to protect the password.

What should you do to increase the security of this device? (Select two.)

Answers:

- ***Use an SSH client to access the router configuration.**
- ***Change the default administrative username and password.**
- Use encrypted Type 7 passwords.
- Use a web browser to access the router configuration using an HTTP connection.
- Use TFTP to back up the router configuration to a remote location.

Explanation:

In this scenario, two key security issues need to be addressed. They are:

- You should use an SSH client to access the router configuration. Telnet transfers data in cleartext over the network connection, exposing sensitive data to sniffing.
- You should change the default administrative username and password. Default usernames and passwords are readily available from websites on the internet.

Encrypted Type 7 passwords on a Cisco device are less secure than those protected with MD5. Using HTTP and TFTP to manage the router configuration could expose sensitive information to sniffers, as these protocols transmit data in cleartext.

q_router_sec_ssh_02_secp8

You've just deployed a new Cisco router that connects several network segments in your organization.

The router is physically located in a locked server closet. You use an FTP client to regularly back up the router configuration to a remote server in an encrypted file. You access the router configuration interface from a notebook computer that is connected to the router's console port. You've configured the device with the username admin01 and the password P@ssW0rd. You have used the MD5 hashing algorithm to protect the password.

What should you do to increase the security of this device?

Answers:

- Use an SSH client to access the router configuration.
- Use encrypted Type 7 passwords.
- Move the router to a secure data center.
- ***Use SCP to back up the router configuration to a remote location.**

Explanation:

In this scenario, the router configuration is being copied to a remote location using an unsecure protocol (File Transfer Protocol) that transfers data in cleartext. You should instead use the Secure Copy Protocol (SCP) to transfer the backup from the router to the remote storage location.

It is not necessary to use an SSH client when using the console port to configure the router.

It is also not necessary to move the device to a data center if it is currently located in a locked server closet.

Encrypted Type 7 passwords on a Cisco device are less secure than those protected with MD5.

6.0 Resiliency and Site Security

6.1 Physical Threats

As you study this section, answer the following questions:

- What types of physical controls can be implemented to protect the perimeter of a building?
- How does an access control vestibule work?
- How are physical access controls similar to technical system security?
- How can environmental design enhance physical security?
- What are four types of sensors and how do they work?

In this section, you will learn to:

- Implement physical security.

The key terms for this section include:

Term	Definition
Physical security	Physical security is the protection of corporate assets from threats such as unauthorized entry, theft or damage.
Access list	A list of personnel who are authorized to enter a secure facility.
Access control vestibule	A specialized entrance with two locking doors that create a security buffer zone between two areas.
Bollard	Bollards are short, sturdy posts used to prevent a vehicle from crashing into a secure area.
Smart card	Access cards that have encrypted access information. Smart cards can be contactless or require contact.
Proximity card	Proximity cards, also known as radio frequency identification (RFID) cards, are a subset of smart cards that use the 125 kHz frequency to communicate with proximity readers.
Biometric Locks	Biometric locks increase security by using fingerprints or iris scans. They reduce the threat from lost keys or cards.
Sensor	A component in an alarm system that identifies unauthorized entry via infrared-, ultrasonic-, microwave-, or pressure-based detection of thermal changes or movement.

Radio frequency ID (RFID)	A means of encoding information into passive tags which can be energized and read by radio waves from a reader device.

This section helps you prepare for the following certification exam objectives:

Exam	Objective

CompTIA Security+ SY0-701	1.2 Summarize fundamental security concepts.
	• Physical security
	  ○ Bollards/barricades
	  ○ Access control vestibule

TestOut Security Pro	2.1 Harden Physical Access 2.1.1 Implement physical security

6.1.1 Physical Security (Lesson Video)

Transcript:

Physical security is an integral aspect of cybersecurity operations, forming the first line of defense against threats targeting an organization's critical assets.

In cybersecurity, the goal is to safeguard digital assets and, equally importantly, the physical components housing these assets, such as servers, data centers, and crucial infrastructure. To effectively understand physical security in cybersecurity, we'll explore some practical examples.
Physical security uses tangible measures to protect digital assets. Access control mechanisms, such as biometric scanners, smart cards, key fobs, and surveillance systems comprising video cameras, motion sensors, and alarms constitute vital components. Biometric scanners, like fingerprint readers, ensure that only authorized personnel gain entry. Surveillance systems function as vigilant sentinels, detecting and alerting against potential threats.
Furthermore, backup power sources, redundant cooling systems, and fire suppression mechanisms play a pivotal role in securing data centers that ensure business continuity in the face of physical disruptions.
The site layout, like a battlefield strategy, arranges the terrain for maximum security.
Fencing acts as the outermost perimeter protection. Effective security fencing is transparent, robust, and resistant to climbing attempts. It serves as a visible boundary.
However, it may impart an intimidating appearance, which may not be ideal for organizations seeking a more welcoming facade.
Security lighting transforms the facility into a well-lit sanctuary, especially during nighttime hours.
It fosters a sense of safety and serves as a deterrent to potential intruders.
The lighting design takes into account overall illumination, specific areas for surveillance purposes, and the avoidance of shadowy or glaring spots.
Barricades help obstruct unauthorized access. They guide individuals through defined entry and exit points, each armed with authentication mechanisms.
In high-risk areas susceptible to attacks, barricades like bollards and security posts are deployed to prevent vehicles from approaching buildings at high speed.
Surveillance mechanisms complement these barricades, identifying any unauthorized attempts at penetration.
Access control vestibules, resembling double-lock security, regulate entry to secure areas. These vestibules comprise two interlocking doors or gates, allowing one person to pass at a time. The first door opens once access is granted via an access control system, such as a card reader or biometric scanner. Only when the first door is securely shut will the second door open, ensuring one-person access. This prevents unauthorized entry or tailgating, an effective security measure commonly seen in data centers, government facilities, and financial institutions.
Access badges replace physical keys with plastic cards embedded with magnetic strips, RFID chips, or NFC technology. These badges grant access through swiping, tapping, or proximity to a reader.
A Physical Access Control System, or PACS, administers this access, controlling entry to specific locations within a building or site. It combines hardware like card readers with software and a centralized control network, logging access activity for security audits and investigations.
In physical security, armed or unarmed, human security guards provide on-ground protection. They verify identification, monitor checkpoints, and apply expertise to potential breaches. Their presence acts as a visual deterrent.
Video surveillance offers cost-effective vigilance, although with certain limitations. Cameras record movements and access but with a slower response. However, they complement security guards and, in some cases, can serve as the primary surveillance method.
Alarms in physical security serve as early warning systems, supplementing other security controls. They detect and notify security personnel and occupants of potential threats, discouraging unauthorized access or criminal activity.
Alarm systems often integrate with access controls, cameras, and motion sensors for a more comprehensive approach.
That's it for this lesson. In this lesson, we discussed how physical security serves as the first line of defense against potential breaches, ensuring that only authorized personnel can access and manipulate network infrastructure. We went through several examples of physical security options like site layout, fencing and lighting to barricades, and entry and exit points. We then looked at how access control vestibules work. Next, we looked at the use of access badges, security guards, and cameras. We finished the lesson going over alarm systems and sensors. By safeguarding the tangible assets that house digital data, physical security forms an essential foundation for comprehensive network security strategies.

6.1.2 Physical Security Facts

Physical security concepts are a critical component of cybersecurity. Physical security measures, such as access control, video surveillance, and environmental controls, help protect an organization's physical assets, including servers, datacenters,

and other critical infrastructure, from unauthorized access, theft, or damage. Effective physical security practices help prevent unauthorized physical access to sensitive data or systems and reduce the risk of insider threats. Organizations must integrate physical security practices into their cybersecurity strategies to provide a layered approach to security and protect against cyber threats that exploit physical vulnerabilities.

This lesson covers the following topics:

- Physical security controls
- Physical security through environmental design
- Gateways and locks
- Access badges
- Security guards and cameras
- Alarm systems and sensors
- Physical attacks

Physical Security Controls

Physical security is critical to cybersecurity operations because it provides the first line of defense against physical access to an organization's critical assets. Cybersecurity is about securing digital assets and protecting the physical components that house those assets, such as servers, data centers, and other critical infrastructure.

Practical examples of physical security measures in cybersecurity operations include access control mechanisms, such as biometric scanners, smart cards, key fobs, and surveillance systems, including video cameras, motion sensors, and alarms. Additionally, backup power, redundant cooling, and fire suppression systems are critical components of physical security in data centers.

Physical access controls depend on the same access control fundamentals as technical system security:

- Authentication—Creates access lists and identifies mechanisms to allow approved persons through the barriers.
- Authorization—Creates barriers around a resource to control access through defined entry and exit points.
- Accounting—Records when entry/exit points are used and detects security breaches.

Physical security is often implemented by incorporating zones. Each zone is separated by its own barrier(s). One or more security mechanisms control entry and exit points through the barriers. Progression through each zone should be increasingly restrictive.

Physical Security Through Environmental Design

Physical security through environmental design is an approach to security that uses the built environment to enhance security and prevent crime. This approach designs physical spaces, buildings, and landscapes to promote non-obvious security features. Physical security via environmental design can be used in various settings, such as residential neighborhoods, commercial districts, schools, and public spaces. By incorporating these design principles, organizations can enhance security, deter criminal activity, and promote a sense of safety and well-being among users. Additionally, physical security via environmental design can be a cost-effective way to improve security because it easily incorporates design elements into new or existing structures at a low cost.

The following table includes some effective environmental design options to enhance physical security:

Device Type	Explanation

Barricades and Entry/Exit Points	A barricade is something that prevents access. As with any security system, no barricade is completely effective; a wall may be climbed, or a lock may be picked. The purpose of barricades is to channel people through defined entry and exit points. Each entry point should have an authentication mechanism so that only authorized persons are allowed through. Effective surveillance mechanisms ensure the detection of attempts to penetrate a barricade by other means. Physical sites at risk of a terrorist attack will use barricades such as bollards and security posts to prevent vehicles from speeding toward a building.
Fencing	The exterior of a building may be protected by fencing. Security fencing needs to be transparent (so guards can see any attempt to penetrate it), robust (so that it is difficult to cut), and secure against climbing (which is generally achieved by making it tall and possibly by using razor wire). Fencing is generally effective, but the drawback is that it gives a building an intimidating appearance. Buildings that are used by companies to welcome customers or the public may use more discreet security methods.
Lighting	Security lighting is enormously important in the perception that a building is safe and secure at night. Well-designed lighting helps to make people feel safe, especially in public areas or enclosed spaces, such as parking garages. Security lighting also acts as a deterrent by making intrusion more difficult and surveillance (whether by camera or guard) easier. The lighting design needs to account for overall light levels, the lighting of particular surfaces or areas (allowing cameras to perform facial recognition, for instance), and avoid areas of shadow and glare.
Bollards	Bollards are generally short vertical posts made of steel, concrete, or other similarly durable materials and installed at intervals around a perimeter or entrance. Sometimes bollards are non-obvious and appear as sculptures or as building design elements. They can be fixed or retractable, and some models can be raised or lowered remotely. Bollards can serve several purposes, such as protecting pedestrians from vehicular traffic, preventing unauthorized vehicle access, and providing perimeter security for critical infrastructure and facilities. They are often used to secure government buildings, airports, stadiums, store entrances, and other public spaces. By preventing vehicles from entering restricted areas, bollards can help mitigate the risks of vehicular attacks and accidents.

There may be a few options to adjust the site layout in existing premises. When faced with cost constraints and the need to reuse existing infrastructure, incorporating the following principles can be helpful:

- Locate secure zones, such as equipment rooms, as deep within the building as possible, avoiding external walls, doors, and windows.
- Position public access areas so that guests do not pass near secure zones. Security mechanisms in public areas should be highly visible to increase deterrence.
- Use signage and warnings to enforce the idea that security is tightly controlled. Beyond basic "no trespassing" signs, some homes and offices also display signs from the security companies whose services they are using. These may convince intruders to stay away.
- Conversely, entry points to secure zones should be discreet. Do not allow an intruder the opportunity to inspect security mechanisms protecting such zones (or even to know where they are). Use industrial camouflage to make buildings and gateways protecting high-value assets unobtrusive or create high-visibility decoy areas to draw out potential threat actors.
- Try to minimize traffic passing between zones. The flow of people should be "in and out" rather than "across and between."

- Give high-traffic public areas high visibility to hinder the covert use of gateways, network access ports, and computer equipment, and simplify surveillance.
- In secure zones, position display screens or input devices away from pathways or windows. Use one-way glass only visible from the inside out so no one can look in through windows.

Gateways and Locks

To secure a gateway it must be fitted with a lock. A secure gateway will normally be self-closing and self-locking rather than dependent on the user to close and lock it. Lock types can be categorized as follows:

- Physical—are conventional locks that prevent the door handle from being operated without using a key. More expensive types offer greater resistance against lock picking.
- Electronic—are locks, rather than a key, that operate by entering a PIN on an electronic keypad. This type of lock is also referred to as cipher, combination, or keyless. A smart lock may be opened using a magnetic swipe card or feature a proximity reader to detect the presence of a physical token, such as a wireless key fob or smart-card.
- Biometric—is a lock integrated with a biometric scanner.

An access control vestibule is a security measure that regulates entry to a secure area. It involves two doors or gates that interlock and permit only one individual to pass through at a time. The first door opens after the person is granted access via an access control system, such as a card reader or biometric scanner. Once the person enters the vestibule, the first door shuts. The second door opens only when the first door is firmly shut. This guarantees only one person can enter or exit at a time, preventing unauthorized access or tailgating. Access control vestibules are frequently used in high-security settings like data centers, government buildings, and financial institutions to offer an additional layer of physical security control. They effectively deter unauthorized access to secure areas and safeguard sensitive assets against potential physical attacks.

Cable locks attach to a secure point on the device chassis. A server chassis might come with both a metal loop and a Kensington security slot. As well as securing the chassis to a rack or desk, the position of the secure point prevents the chassis from being opened without removing the cable first.

Access Badges

Access badges are a fundamental component of physical security in larger organizations where control over access to various locations is critical. Plastic cards embedded with magnetic strips, radio frequency identification (RFID) chips, or near - field communication (NFC) technology are issued to authorized individuals, such as employees, contractors, or visitors instead of physical keys. Access badges replace physical keys but provide access similarly. This is achieved by requiring the badge to be swiped, tapped, or brought into proximity with a reader at the access point, like a door or turnstile. The reader communicates with a control system to verify the badge's authenticity and the level of access granted to the badge holder. If the system recognizes the badge as valid and authorized for that area, the door unlocks, granting access.

It is important to note that implementing this type of access control system requires magnetic door-locking mechanisms and access card readers, which depend upon electrical power and network communications at each access point (such as a doorway.)

A physical access control system (PACS) is a critical component in managing and maintaining security within a facility. It is a system designed to control who can access specific locations within a building or site. The PACS operates through a combination of hardware and software, including access cards or badges, card readers, access control panels, and a centralized control network. The PACS system provides valuable badge access activity logging capabilities.

In addition to controlling access, access badges also serve as a form of identification, displaying pertinent information about the badge holder, such as their name, title, and photograph. This aids in quickly identifying individuals within a facility and verifying that they are in an area appropriate for their role or purpose. Moreover, access badges can provide valuable data for security audits and investigations. Each time a badge is used, a PACS system can log the time, location, and identity

associated with the access event. This can be crucial in investigating security breaches, understanding movement patterns, and even planning emergency evacuation strategies.

Security Guards and Cameras

Surveillance is typically a second layer of security designed to improve the resilience of perimeter gateways. Surveillance may be focused on perimeter areas or within security zones. Human security guards, armed or unarmed, can be placed in front of and around a location to protect it. They can monitor critical checkpoints and verify identification, allow or disallow access, and log physical entry events. They also provide a visual deterrent and can apply their knowledge and intuition to potential security breaches. The visible presence of guards is a very effective intrusion detection and deterrence mechanism, but it is correspondingly expensive. It may not be possible to place security guards within certain zones because they cannot be granted the appropriate security clearance. Training and screening of security guards is imperative.

Video surveillance is a cheaper means of providing surveillance than maintaining separate guards at each gateway or zone, though it is still not cheap to set up if the infrastructure is not already in place on the premises. It is also quite an effective deterrent. The other big advantage is that movement and access can be recorded. The main drawback compared to the presence of security guards is that response times are longer, and security may be compromised if not enough staff are in place to monitor the camera feeds.

The cameras in a CCTV network are typically connected to a multiplexer using coaxial cabling. The multiplexer can then display images from the cameras on one or more screens, allow the operator to control camera functions and record the images to tape or hard drive. Newer camera systems may be linked in an IP network using regular data cabling.

Camera systems and robotics can use AI and machine learning to implement smart physical security:

- Motion Recognition—Occurs when the camera system is configured with gait identification technology. This means the system can generate an alert when anyone within sight of the camera moves in a pattern that does not match a known and authorized individual.
- Object Detection—Occurs when the camera system can detect changes to the environment, such as a missing server or unknown device connected to a wall port.
- Drones/UAV—cameras mounted on drones can cover wider areas than ground-based patrols.

Alarm Systems and Sensors

Alarms play a vital role in physical security by supplementing other security controls. Alarms alert security personnel and building occupants of potential threats or breaches. They are both detective and deterrent controls, notifying of trouble and discouraging unauthorized access and criminal activity. Alarms are often integrated with other physical security controls, such as access control systems, surveillance cameras, or motion sensors, to enhance their effectiveness. The following list describes several common types of alarms:

- Circuit—Uses a circuit-based alarm that sounds when the circuit is opened or closed, depending on the type of alarm. For example, this could be a door or window opening or by a fence being cut. A closed-circuit alarm is more secure because it cannot be defeated by cutting the circuit like an open-circuit alarm.
- Motion Detection—Uses a motion-based alarm linked to a detector that is triggered by any movement within an area such as a room (defined by the sensitivity and range of the detector). The sensors in these detectors are either microwave radio reflection (similar to radar) or passive infrared (PIR), which detect moving heat sources.
- Noise Detection—Uses an alarm triggered by sounds picked up by a microphone. Modern AI-backed analysis and identification of specific types of sound can render this type of system less prone to false positives.
- Proximity—Uses radio frequency ID (RFID) tags and readers to track the movement of tagged objects within an area. This allows an alarm system to detect whether someone is trying to remove equipment.
- Duress—Uses an alarm triggered manually by staff if they come under threat. There are many ways of implementing this type of alarm, including wireless pendants, concealed sensors or triggers, and DECT

handsets or smartphones. Some electronic entry locks can also be programmed with a duress code different from the ordinary access code. This will open the gateway but also alert security personnel that the lock has been operated under duress.

Circuit-based alarms are suited for use at the perimeter and on windows and doors. These may register when a gateway is opened without using the lock mechanism properly or when a gateway is held open for longer than a defined period. Motion detectors are useful for controlling access to spaces not normally used. Duress alarms are useful for exposed staff in public areas. An alarm might simply sound like an alert or be linked to a monitoring system. Many alarms are linked directly to local law enforcement or third-party security companies. A silent alarm alerts security personnel rather than sounding an audible alarm.

Sensor Types

Sensors are critical in implementing physical security measures, providing proactive detection and alerting capabilities against potential security breaches. These devices can employ various technologies, including infrared, pressure, microwave, and ultrasonic systems, each with unique advantages and suitable applications.

- Infrared sensors are commonly used in motion detection systems. They detect changes in heat patterns caused by moving objects, such as a human intruder. These are often used in residential and commercial security systems, triggering alarms or activating security lights when detecting motion.
- Pressure sensors are typically installed inside floors or mats and are activated by weight. They can be used in high-security areas to detect unauthorized access or even in retail environments to count foot traffic.
- Microwave sensors emit microwave pulses and measure the reflection off a moving object. They are often combined with infrared detectors in dual-technology motion sensors. These sensors are less likely to trigger false alarms, as the infrared and microwave sensors must be tripped simultaneously to trigger an alarm. These can be useful in securing large outdoor areas like parking lots or fenced areas.
- Ultrasonic sensors emit sound waves at frequencies above the range of human hearing and measure the time it takes for the waves to return after hitting an object. They are often used in automated lighting systems to switch lights on when someone enters a room and switch them off again when the room is empty.

Physical Attacks

A physical attack is one directed against cabling infrastructure, hardware devices, or the environment of the site facilities hosting the network.

The following table include three of the most common physical attacks.

Attack	Explanation
Brute Force	A brute force physical attack can take several different forms, some examples of which are the following: • Smashing a hardware device to perform physical denial of service (DoS). • Breaking into premises or cabinets by forcing a lock or gateway. This is likely to be an indicator of theft or tampering. Preventing theft is often impossible to guarantee, so knowing that something has been stolen is important for things like data breach reporting and revoking access permissions. A system that is tamper-evident will display visible signs of forced entry or use that are difficult for a threat actor to disguise.

Environmental	An environmental attack could be an attempt to perform denial of service. For example, a threat actor could try to destroy power lines, cut through network cables, or disrupt cooling systems. Alternatively, environmental and building maintenance systems are known vectors for threat actors to try to gain access to company networks. The risk from physical attacks means that premises must be monitored for signs of physical damage or the addition of rogue devices.
RFID Cloning	Radio Frequency ID (RFID) is a means of encoding information into passive tags. When a reader is within range of the tag,it produces an electromagnetic wave that powers up the tag and allows the reader to collect information from it. This technology can be used to implement contactless building access control systems. RFID cloning and skimming refer to ways of counterfeiting contactless building access cards or badges: • Cloning —this refers to making one or more copies of an existing card. A lost or stolen card with no cryptographic protections can be physically duplicated. Card loss should be reported immediately so that it can be revoked and a new one issued. If there were a successful attack, it might be indicated by use of a card in a suspicious location or time of day. • Skimming —this refers to using a counterfeit reader to capture card or badge details, which are then used to program a duplicate. Some types of proximity card can quite easily be made to transmit the credential to a portable RFID reader that a threat actor could conceal on their person. These attacks can generally only target "dumb" access cards that transfer static tokens rather than perform cryptoprocessing. If use of the cards is logged, compromise might be indicated by impossible travel and concurrent use access patterns. Near-field communication (NFC) is derived from RFID and is also often used for contactless cards. It works only at very close range and allows two-way communications between NFC peers.

6.1.3 Implement Physical Security (Simulation)

Scenario

Based on a review of physical security at your office, you have recommended several improvements. Your plan includes installing smart card readers, IP cameras, signs, and an access log book.

In this lab, your task is to:

Implement your physical security plan by dragging the correct items from the shelf onto the various locations in the building. As you drag the items from the shelf, the possible drop locations are highlighted. To implement your plan, you must:

- Install two IP security cameras in the appropriate location to record which employees access the key infrastructure. The security cameras should operate over the TCP/IP network.
- Install the smart card key readers in the appropriate locations to control access to key infrastructure. The key card readers should be contactless and record more information than the card's ID.
- Install a Restricted Access sign on the networking closet door to control access to the infrastructure.
- Place the visitor log on the lobby desk.

Not all items on the shelf will be used.

Explanation

Complete this lab as follows:

1. Install the IP security cameras:
    a. From the Shelf, expand **CCTV Cameras** .
    b. Drag the IP Security Camera from the Shelf to the highlighted circle inside the networking closet.
    c. Drag the IP Security Camera from the Shelf to the highlighted circle just outside the networking closet.
2. Install the smart card key readers:
    a. From the Shelf, expand **Door Locks** .
    b. Drag a smart card reader from the Shelf to the highlighted location outside the building's front door.
    c. Drag a smart card reader from the Shelf to the highlighted location outside the networking closet's door.
3. Install the Restricted Access sign:
    a. From the Shelf, expand **Restricted Access Signs** .
    b. Drag the Restricted Access sign from the Shelf to the networking closet door.
4. Place the visitor log on the lobby desk:
    a. From the Shelf, expand **Visitor Logs** .
    b. Drag the visitor log from the Shelf to the lobby desk.

6.1.4 Practice Questions (Section Quiz)

q_phys_sec_badges_01_secp8

Which of the following are solutions that address physical security? (Select two.)

Answers:

- ***Require identification and name badges for all employees.**
- Implement complex passwords.
- Disable guest accounts on computers.
- ***Escort visitors at all times.**
- Scan all floppy disks before use.

Explanation:

Physical security controls physical access to the network or its components. Physical security controls include:

- Requiring identification or key cards before entry is permitted.
- Escorting visitors at all times.
- Keeping doors and windows locked.
- Keeping devices with sensitive information out of view of public users.
- Keeping the server room locked (locking computers to racks or tables to prevent theft).

Implementing complex password, disabling guest accounts on computers, and scanning all floppy disks before use are not considered physical security controls.

q_phys_sec_badges_02_secp8

You are the security administrator for a small business. The floor plan for your organization is shown in the figure below.

You've hired a third-party security consultant to review your organization's security measures. They have discovered multiple instances where unauthorized individuals have gained access to your facility, even to very sensitive areas. They recommend that you provide employees with access badges and implement access badge readers to prevent this from happening in the future.

Click on the office locations where access badge readers would be most appropriate.

Answers:

- ***162,137,131,132**
- ***315,40,112,104**
- 22,40,112,104
- 135,20,179,114
- 22,144,139,114
- 294,144,139,114

Explanation:

Access badge readers are typically implemented at building entrances to control access to a facility. Only individuals who have an authorized access badge are allowed to enter the facility. Individuals who do not have an access badge must be cleared and admitted by security personnel. Additional access badge readers can be implemented within the facility to further restrict access to sensitive areas, such as the server room.

q_phys_sec_biometric_secp8

If a fingerprint or retina scan is required to open a secured door, which kind of physical security has been implemented?

Answers:

- Access list
- Mantrap
- ***Biometric locks**
- Double-entry door

Explanation:

Biometric locks use unique physical characteristics of a person to authenticate his or her access to a secured item. Often, these locks take the form of fingerprint scanners or retina scanners.

An access list is incorrect because it is a list of names that a guard checks.

Mantraps and double-entry doors are also incorrect because they are styles of entryways and don't check physical characteristics.

q_phys_sec_bollards_secp8

A security manager decides to enhance the physical security of a warehouse storing high-value tech equipment by installing a deterrent at the perimeter to prevent vehicle-based attacks.

Which security measure would be the MOST suitable for this purpose?

Answers:

- ***Bollards**
- Access badge
- Access control vestibule
- Fencing

Explanation:

Bollards are short vertical posts that serve as an effective barrier against vehicle-based attacks. Their sturdy design stops vehicles from entering sensitive areas, making them the most suitable choice for preventing vehicle-based attacks.

An access badge does not serve to deter vehicle-based attacks. Its primary function is to verify the identity of individuals and grant or deny access based on their authorization levels.

An access control vestibule effectively controls pedestrian access but does not provide any substantial deterrent against vehicle-based attacks.

Fencing can serve as a physical barrier to prevent unauthorized access. However, compared to bollards, it is less effective against vehicle-based attacks, especially if the vehicles are large or moving at high speed.

q_phys_sec_cctv_01_secp8

Which option is a benefit of CCTV?

Answers:

- Reduce the need for locks and sensors on doors.
- ***Expand the area visible by security guards.**
- Provide a corrective control.
- Increase security protection throughout an environment.

Explanation:

A primary benefit of CCTV is that it expands the area visible by security guards. This helps few guards oversee and monitor a larger area.

CCTV does not reduce the need for locks and sensors on doors and does not provide a corrective control (it is a preventative, deterrent, or detective control). CCTV does not increase security protection throughout an environment, as the range is limited to areas over which it is aimed.

q_phys_sec_cctv_02_secp8

You want to use CCTV to increase your physical security, and you want the ability to remotely control the camera position.

Which camera type should you choose?

Answers:

- ***PTZ**

- Bullet
- C-mount
- Dome

Explanation:

A Pan Tilt Zoom (PTZ) camera lets you dynamically move the camera and zoom in on specific areas (cameras without PTZ capabilities are set looking a specific direction). Automatic PTZ mode automatically moves the camera between several preset locations. Manual PTZ lets an operator remotely control the position of the camera.

A bullet camera has a built-in lens and is long and round in shape. Most bullet cameras can be used indoors or outdoors. A c-mount camera has interchangeable lenses, is typically rectangular in shape, and carries the lens on its end. Most c-mount cameras require special housing to be used outdoors. A dome camera is a camera protected with a plastic or glass dome. These cameras are more vandal-resistant than other cameras.

Bullet, c-mount, or dome cameras can also be PTZ cameras.

q_phys_sec_cctv_03_secp8

A tech company recently moved to a new facility and seeks to bolster its physical security posture. The security team proposes integrating security guards and surveillance cameras as part of the security measures.

The chief security officer (CSO) wants to ensure these implementations effectively deter, detect, and report potential security incidents.

Given the scenario, which actions will maximize the effectiveness of security guards and cameras in enhancing the organization's physical security? (Select two.)

Answers:

- ***Position cameras to monitor critical access points and sensitive areas.**
- Allow security guards to monitor camera feeds only during break times.
- ***Implement security guard rotations and unannounced spot checks.**
- Place cameras in highly visible areas, but do not connect them to any recording device.
- Place two cameras on the locations where there are security guards positioned.

Explanation:

Positioning cameras to monitor critical access points and sensitive areas ensures comprehensive surveillance, enhancing deterrence and detection capabilities.

Implementing security guard rotations and unannounced spot checks prevents complacency and ensures guards remain vigilant, enhancing the detection and reporting of incidents.

Allowing security guards to monitor camera feeds only during break times reduces the effectiveness of real-time surveillance, making this measure counterproductive.

While visible cameras can act as a deterrent, not connecting them to any recording device negates their primary purpose of recording potential incidents for later review or evidence collection.

Placing cameras (one or more) on the locations where security guards are positioned, does not necessarily enhance physical security, as the security guards already provide significant security. It would be wiser to place two cameras in areas where there are no security guards located.

q_phys_sec_door_secp8

Which of the following controls is an example of a physical access control method?

Answers:

- ***Locks on doors**
- Access control lists with permissions
- Passwords
- Smart cards
- Hiring background checks

Explanation:

Locks on doors are an example of a physical access control method. Physical controls restrict or control physical access.

Passwords, access control lists, and smart cards are all examples of technical controls.

Even though a smart card is a physical object, the card by itself is a part of a technical implementation.

Requiring background checks for hiring is an example of a policy or an administrative control.

q_phys_sec_fencing_secp8

A data center must enhance its security measures to prevent unauthorized access to its facility. The center are considering different methods to achieve this goal.

What should the data center implement first to ensure a strong physical barrier against intrusions?

Answers:

- ***Fencing**
- Biometric authentication
- Security guard patrols
- Video surveillance

Explanation:

Fencing serves as a first line of defense in physical security, creating a physical barrier that prevents or discourages unauthorized access to the facility. It not only restricts intrusions but also acts as a psychological deterrent.

Biometric authentication effectively controls access inside the data center, although it is not a primary physical barrier against intrusions from outside.

Security guard patrols are not considered a physical barrier and thus do not provide the initial deterrence that fencing does.

Video surveillance is not a physical barrier to entry and therefore does not provide the initial deterrence that fencing offers.

q_phys_sec_gateways_locks_secp8

A major technology company plans to renovate its headquarters, emphasizing both physical and digital security.

The head of the security department is looking to enhance the building's main entry points and contemplates integrating advanced gateways with innovative locking mechanisms.

In relation to securing a major technology company's main entry points, which approaches will BEST harness the potential of gateways and locks to ensure optimal security? (Select two.)

Answers:

- ***Employ network gateways that scrutinize incoming traffic for malicious activity.**
- ***Implement biometric locks that grant access based on unique physiological characteristics.**
- Use gateways to redirect all visitors to the company's promotional website.
- Install traditional padlocks that require a standard key.
- Install CCTV cameras to increase the effectiveness of the gateways and locks.

Explanation:

Network gateways that evaluate incoming traffic for potentially harmful activity effectively act as an organization's first line of digital defense, thereby safeguarding the company's internal network resources.

Biometric locks enhance physical security by leveraging unique physiological traits, such as fingerprints or retina scans, thus reducing the likelihood of unauthorized access.

Redirecting visitors to a promotional website does not improve security. Instead, gateways should prioritize security over promotional activities.

Traditional padlocks with standard keys do not offer the advanced security necessary for a major technology company, as potential threat actors can easily duplicate or pick them.

Installing CCTV cameras can help in monitoring secured areas, but it does not necessarily increase the effectiveness of the gateways and locks.

q_phys_sec_infrared_sensor_secp8

To increase the physical security of a secured location, an organization deploys motion detection sensors throughout the grounds and building.

What type of sensor uses this technology?

Answers:

- ***Infrared sensor**
- Pressure sensor
- Microwave sensor
- Ultrasonic sensor

Explanation:

In this instance, the organization would install infrared sensors commonly used in motion detection systems. They can detect changes in heat patterns caused by moving objects, such as a human intruder.

While effective but not used to detect motion, pressure sensors activate when applying weight to the sensor.

Microwave sensors emit microwave pulses and measure the reflection of a moving object. However, they would also need infrared sensors to trigger simultaneously to use as motion detection.

Not ideal in this situation, ultrasonic sensors emit sound waves at frequencies above the range of human hearing and measure the time it takes for the waves to return after hitting an object.

q_phys_sec_layered_secp8

The cybersecurity team at a multinational corporation is collaborating with the facilities department to design a new data center. The team seeks to integrate top-tier physical security controls into the site layout to maximize protection against potential threats.

The discussions revolve around the BEST strategies to ensure the safety of the data center.

When designing the physical security controls for the site layout of the new data center, which strategy would be MOST effective in deterring unauthorized access and providing a comprehensive security layer?

Answers:

- ***Establishing a security perimeter with layered access controls**
- Implementing a single, fortified main entrance
- Placing all servers near windows for easy maintenance
- Distributing security personnel evenly throughout the premises

Explanation:

Layered access controls, often referred to as "defense in depth," ensure that multiple levels of security mechanisms are in place. If one fails or gets bypassed, others still provide protection.

While a fortified entrance can be a strong deterrent, relying solely on one point of entry without layered controls can lead to vulnerabilities. Single points of failure are generally not advisable.

Positioning servers near windows can expose them to potential threats, such as visual hacking or physical breaches. It is counterproductive from a security perspective.

While security personnel are important, their distribution should be strategic, focusing on critical points rather than a mere even spread. Layered access controls would still be more effective.

q_phys_sec_rfid_cloning_secp8

As the head of physical security at a large tech company, you have been tasked with investigating a series of unauthorized entries into secure areas of your facilities.

The intrusions have been sporadic and seemingly random, with no clear pattern or motive. The intruders have not been caught on camera, and no physical damage or theft has been reported. However, you notice that the access logs show entries made using the credentials of employees who were not on-site at the time of the incidents.

Which of the following is the MOST likely method the intruders are using to gain access?

Answers:

- Lock picking

- Social engineering
- ***RFID cloning**
- Bypassing CCTV cameras

Explanation:

RFID cloning is the most likely method used by the intruders. RFID cloning involves copying the data from an employee's RFID access card and using it to create a duplicate card. This would explain the access logs showing entries made using the credentials of employees who were not on-site at the time, as the intruders could be using cloned cards to gain access.

Lock picking is unlikely to be the method used as the access logs show entries made using employee credentials. Lock picking would not leave such a trace.

While social engineering could potentially explain the unauthorized entries, it would not account for the access logs showing entries made using the credentials of employees who were not on-site at the time.

While bypassing CCTV cameras could potentially allow the intruders to avoid detection, it would not explain the access logs showing entries made using the credentials of employees who were not on-site at the time.

q_phys_sec_smartcards_secp8

Which kind of access control technology allows more than just the identity of an individual to be transmitted wirelessly to either allow or deny access?

Answers:

- Proximity card
- ***Smart card**
- Biometric locks
- Keypad locks

Explanation:

Unlike proximity cards that only transmit the owner's identity, smart cards can contain and transmit many more pieces of information.

Biometric locks and keypad locks don't transmit data wirelessly. In contrast, they require physical interaction.

q_phys_sec_vestibule_secp8

A company wants to improve the physical security at its headquarters. They need a solution that can help regulate access to the building and deter potential intruders during nighttime.

Which physical security measure should they prioritize?

Answers:

- ***Access control vestibule**
- Enhanced lighting
- Closed-circuit television (CCTV)
- Perimeter fencing

Explanation:

An access control vestibule is a two-door system where the first door must close before the second opens, effectively controlling and managing access to the building.

Lighting can deter potential intruders during nighttime by illuminating dark areas, but it does not regulate access to the building.

CCTV can provide surveillance and record activity around the building, but it does not regulate access to the building. CCTV provides a way to monitor and record activities but does not control who can enter the building.

Perimeter fencing can deter potential intruders and control access to a property to an extent. However, it does not regulate access to the building in a controlled manner as an access control vestibule does.

6.2 Monitoring and Reconnaissance

As you study this section, answer the following questions:

- What is the goal of network monitoring?
- What is the difference between passive and active reconnaissance?
- What tool is a search engine for internet-connected devices?
- What are common techniques used in active reconnaissance?

In this section, you will learn to:

- Perform port and ping scans.
- Perform reconnaissance with Nmap.

The key terms for this section include:

Term	Definition
IP scanners	Special tools that allow a network administrator to scan the entire network to find all connected devices and their IP addresses.
Reconnaissance	Also known as *footprinting* . This is the process of gathering information about a target before beginning any penetration test or security audit.
Active reconnaissance	The process of gathering information by interacting with the target in some manner.
Passive reconnaissance	The process of gathering information about a target with no direct interaction with the target.
Packet sniffing	The act of capturing data packets transmitted across the network and analyzing them for important information.

War driving	The act of driving around with a wireless device looking for open vulnerable wireless networks.
War flying	The act of using drones or unmanned aerial vehicles to find open wireless networks.
Eavesdropping	The act of covertly listening in on a communication between other people.
Open-Source Intelligence (OSINT)	Any data that is collected from publicly available sources such as social media, search engines, company websites, media sources, or public government sources.

This section helps you prepare for the following certification exam objectives:

Exam	Objective

CompTIA Security+ SY0-701	2.2 Explain common threat vectors and attack surfaces.
	• Unsecure networks
	• Open service ports
	
	2.5 Explain the purpose of mitigation techniques used to secure the enterprise.
	• Monitoring
	
	4.1 Given a scenario, apply common security techniques to computing resources.
	• Monitoring
	
	4.3 Explain various activities associated with vulnerability management.
	• Identification methods
	  ○ Open-source intelligence (OSINT)
	
	4.4 Explain security alerting and monitoring concepts and tools.
	• Monitoring computing resources
	  ○ Systems
	  ○ Infrastructure
	  ○ Infrastructure
	• Tools
	  ○ Vulnerability scanners
	
	4.5 Given a scenario, modify enterprise capabilities to enhance security.
	• Firewall
	  ○ Ports/protocols

	4.9 Given a scenario, use data sources to support an investigation.
	• Data sources
	  ○ Packet captures
	5.4 Summarize elements of effective security compliance.
	• Compliance monitoring
	5.5 Explain types and purposes of audits and assessments.
	• Internal
	  ○ Compliance
	• Penetration testing
	  ○ Reconnaissance
	  ▪ Passive
	  ▪ Active

TestOut Security Pro	2.2 Harden network devices 2.2.4 Harden a wireless network

6.2.1 Network Monitoring (Lesson Video)

Transcript:

Keeping an eye on the type of traffic that flows across your network helps you to better understand what's going on in your system. If you know your network and constantly monitor it, you can catch attackers before they do any significant damage. In this lesson, we'll look at some common network monitoring tools and how they can be used.

One of the more common network tests is a connection test. The command line utility named ping is the easiest way to do this. The ping utility sends an ICMP packet from our computer to another device on our network and waits for a response. If we get a response, the device is connected and active. If there's no response, it means the device could be offline or something is blocking the reply packets, and we need to figure out why. Ping is used in pretty much all operating systems.
Traceroute is a tool that allows us to see the path that a packet takes. Every device the packet travels through to its destination is known as a hop. The traceroute utility helps us determine if there's a specific device in our network that's down and causing problems for us. Traceroute is the command used in Linux and tracert is the command for Windows. The Linux version defaults to sending UDP packets and Windows uses ICMP packets. Other than that, these tools do exactly the same thing.
Pathping is a Windows command line tool that essentially combines the ping and tracert tools. The pathping utility sends ICMP packets to check connectivity, but it also gives us information such as latency and packet loss about each and every hop a packet takes. We can also use pathping to see if certain router connections are dropping packets before they reach their desired destination.
The netstat command shows us all sorts of network statistics. When we run this command, we receive a snapshot of our TCP connections, which ports they're connected to, the programs that are using those connections, and other statistics. We can use this information to monitor our traffic and make sure that our computer isn't connected to places it shouldn't be.
The route command is used in both Linux and Windows to show us our routing table and to allow us to make manual changes to it. Routers use the routing table to determine where to send packets. If there's an issue with the routing table, the route command can help us find it and make the necessary changes.

The arp command is another command used in basically all operating systems. ARP stands for Address Resolution Protocol, and its purpose is to match IP addresses to MAC addresses. The arp command allows us to view and modify the ARP table entries on our local computer. We can use this information to discover and correct any duplicate IP addresses or invalid entries that might cause connection issues.
One of the biggest reasons for connectivity issues is an improperly configured Domain Name System, or DNS. DNS is what's responsible for matching IP addresses to website or computer names. If we're running a web server, we absolutely need to make sure that our DNS entries are correct or no one will be able to connect. Even in an internal network, an improperly configured DNS can cause devices to be unable to connect to the server. We use the nslookup command in Windows or the dig command in Linux to view and modify our DNS settings.
Another big reason for connectivity issues is the IP configuration on the local computer. To view current information about our local system, we use the ipconfig command in Windows and the ifconfig command in Linux. These commands show us the current IP address, subnet mask, default gateway, and more. We can use this information to correct DHCP issues or static IP configurations.
Hping is a security tool that can be used to send ICMP packets as well as TCP, UDP, and RAW IP packets. Aside from simply checking connectivity, hping is used to analyze the target system to gather more information on it. The hping command is primarily designed for Linux but can be installed on Windows as well.
Netcat is an extremely powerful security tool that can basically do anything with TCP. Netcat is able to open up a TCP connection between two devices and send UDP packets between them, scan for open ports, and even listen in on connections between individual ports.
IP scanners are tools that allow us to scan our entire network in order to find all connected devices and their IP addresses. Depending on the program, these tools pull up basic-to-advanced information such as routes, hostnames, operating systems, and more.
Nmap is another powerful network monitoring tool. Nmap is a command line utility, but there is a GUI-based version called Zenmap. We can use nmap to scan an entire network or a specific IP address to discover all sorts of information like open ports, running services, operating system information, and beyond. One thing that makes nmap so powerful is that it can scan with different protocols on individual networks.
That'll wrap up this lesson. In this video, we covered a variety of tools and commands we can use to monitor and manage our network. It's important that we know each of these tools and how they're used so that we can pick the best tool for our situation.

6.2.2 Network Monitoring Facts

This lesson covers the following topics:

- Network monitoring overview
- Network monitoring tools

Network Monitoring Overview

The goal of monitoring is to keep track of conditions on the network, identify situations that might signal potential problems, pinpoint the source of problems, and locate areas of your network that might need to be upgraded or modified.

As you monitor your network, look for the top talkers and listeners.

- Top talkers are computers that send the most data, either from your network or into your network.
- Top listeners are hosts that are receiving most of the data by streaming or downloading large amounts of data from the internet.

It is important to know which computers are the big receivers and senders of information because it is a good way to tell if something is wrong on your network. An unauthorized system that is sending large amounts of data to locations outside of your network could be a sign of a data breach.

Monitoring also plays a vital role in endpoint hardening, helping to enforce and maintain the security measures put in place during the hardening process. Once devices are hardened, monitoring helps to ensure these conditions remain in place.

Security analysts can detect changes that weaken the hardened configuration through continuous monitoring. For instance, if a previously disabled port is detected as open or a service that was disabled is changed to enabled, monitoring tools can alert analysts of the change—which may indicate a breach.

Additionally, monitoring can provide valuable data for compliance and auditing purposes. Regular reports on the status of endpoint devices can verify that hardening baselines have been effectively deployed and maintained, supporting compliance with various regulations and industry standards.

Network Monitoring Tools

The below table lists some of the tools used to monitor the health of a network:

Tool	Description
ping	Ping is a command line tool that is used to perform a connection test between two network devices. Ping works by sending ICMP packets to a specified device on the network and waiting for a response. This shows if there is a connection issue or not. The syntax for the ping command is: **ping <target IP address or hostname>** The following switches are the more common switches that can be used to modify the ping command: • **-t** sends ICMP packets until manually stopped. • **-a** resolves addresses to hostnames. • **-n <*count*>** specifies the number of ICMP packets to send. Ping sends 4 packets by default • **-l <*size*>** specifies the packet size in bytes. ping sends 32-byte packets by default
tracert/traceroute	The tracert tool shows the path a packet takes to reach its destination. Every device the packet passes through is known as a hop. Use tracert to locate network devices that are down or causing latency issues. • tracert is the Windows version and sends ICMP packets. • traceroute is used in Linux and sends UDP packets.
pathping	The pathping Windows command line tool combines the tracert and ping tools. Use pathping to locate network devices that are down or causing latency issues.
netstat	Use the netstat command to display a variety of network statistics in both Windows and Linux, including: • Connections for different protocols • Open ports • Running programs Some of the common switches used to specify the information shown in Windows are:

	• **-a** displays all connections and listening ports. • **-b** displays the executable involved in creating each connection or listening port. • **-f** displays the FQDN for the foreign address if possible. • **-r** displays the routing table • **-p <*protocol*>** shows the connections for a specified protocol (TCP, UDP, TCPv6, UDPv6)
route	The route command is used in both Windows and Linux to show the routing table and to make manual changes to the table.
arp	The arp command is used in both Windows and Linux. ARP stands for Address Resolution Protocol and is used to match IP addresses to MAC addresses. The arp command displays, adds, and removes arp information from network devices. Some of the common switches used with the arp command are: • **-a** displays current ARP entries. • **inet_addr** specifies an internet address • **-d** deletes the host specified by inet_addr
nslookup/dig	The nslookup and dig commands are used to view and modify DNS settings. These tools can be used to look up DNS server information and also give IP addresses and domain names for a network server. • nslookup is used in Windows. • dig is used in Linux.
ipconfig/ifconfig	The ipconfig command (Windows) and the ifconfig command (Linux) are used to display the IP configuration on the local computer. Information such as the following can be shown using these commands: • Adapter name • Adapter MAC address • If DHCP is enabled or not • IPv6 address • IPv4 address • Subnet mask • IP lease information • Default gateway • DHCP server • DNS server
hping	Hping is a security tool that can check connectivity and also analyze the target to gather information. Hping can send ICMP, TCP. UDP, and RAW-IP packets. Hping is primarily designed for Linux but can be installed in Windows.

netcat	The netcat security tool can read and write data across both TCP and UDP network connections. It opens a TCP connection between two devices and can be used to send packets, scan for open ports, and listen in on connections to specific ports. You can download netcat from the internet.
IP scanners	IP scanners are special tools that allow a network administrator to scan the entire network to find all connected devices and their IP addresses. Advanced scans can also display information such as: • Routes • Hostnames • Operating systems
nmap	The nmap utility is a network security scanner. Use nmap to scan an entire network or specific IP addresses to discover all sorts of information such as: • Open ports • Running services • Operating system Nmap can use many different protocols and options depending on the network or device being scanned. Nmap is a command line tool, but a GUI version called Zenmap is available.

6.2.3 Performing Port and Ping Scans (Demo Video)

Transcript:

In this demo, we're going to look at Zenmap. Zenmap is the GUI equivalent of Nmap, which is a command line tool. We've downloaded and installed Zenmap for Windows. Even though Zenmap has a graphical user interface, we still use the familiar commands that Nmap uses. Other than that, the interface is quite simple.

First, you want to identify the target of your scan. In this case, it might be 192.168.2.1, a specific IP address, or maybe a range of IP addresses using CIDR notation. It's going to make sure that these first three octets stay the same, 192.168.2, then we'll try .1 and so on all the way up to .255 for the last octet.
To the right here, you can see what type of scan you want to perform. Right now, it's listed as an intense scan. To start out, I'm going do a lighter scan. You can see you have Intense Scan, plus UDP, plus all the TCP ports, without the ping, etc. You have the ping, the quick scan, the quick scan plus, and on and on. There's lots of different options here.
I'm going to start out with just a ping scan, which will simply see if the hosts in this IP address range respond to a ping. To do this, I'll simply select that option and then click on Scan. This will only take a few seconds to complete, as it's a very lightweight scan. You'll see here, as it goes on, that we'll start to populate the operating systems and the hosts associated with those IP addresses to the left.
In this case, we haven't done a deep scan. We don't know the operating systems on these hosts or other details yet. But we can see all the hosts that are in that range that responded to the ping scan. Maybe we come down and say, "Hey, this IP address is something of interest." Then we can go and do an intense scan with that specific host.
Before I do that, let me show you here that there's not really a lot we know about this host right now. We know its MAC address, its IP address, and whether it's currently up, but we don't know anything else.
You could do this intense scan with a full range of IP addresses. It'll just take a while. In the interest of time, I'll just do an intense scan on that single IP address.

This takes about four or five minutes to complete depending on the responsiveness of the server, so I'll stop the demo while it runs. But you can see that it's starting to discover open ports, different TCP ports, and it'll run through a variety of different scripts to try to discover information about this host.
When all is said and done, we should be able to see what type of operating system it is, even the version of the operating system, and other things that it uses as it discovers open ports. It can query those ports and ask certain questions in order to receive responses and determine the types of services that are running on this machine. We'll go ahead and pause now until that script is complete.
You can see that it's completed the scan. Let's look through some of these results first. We'll start at the top. It scanned for specific ports, and it started a service scan and gathered some information. It was looking for 20 specific services. It took about a minute to do that. Then it tried to detect the operating system and a variety of other services. It looks at the specific ports and tries to determine which programs are actually running. This server has DNS server. It's actually Microsoft's DNS server. Because of the types of queries that Nmap puts out, you can see the types of services that are actually running. We know that it's Microsoft DNS. We know Microsoft IIS, the web server, is running there, and we know the version of that web server and a variety of other services that are currently running.
Some remote procedure calls on certain ports that are open, and a variety of other information like the net BIOS names and the server versions. We can get quite a bit of detail using Nmap and the associated GUI. Let's click on 15. You can see that we have a summary of information for that. It's Windows, and it has the last boot time. It was back on May 9th. That's several months ago. Then we have the versions and other information. This is a great tool that you can use to quickly gather information about a network. It's easy to see why these tools make it so easy to attack and hack, or at least understand the composition of the machines within a network.
All right, that's it for this demo--just a quick demo of Nmap and the associated Zenmap GUI and how you can do ping scans and port scans using this tool.

6.2.4 Reconnaissance (Lesson Video)

Transcript:

Reconnaissance, which is also known as Footprinting, is the process of gathering information about a target before you begin an attack. There are two types of reconnaissance, passive and active. Passive reconnaissance is gathering information without directly interacting with users, and active reconnaissance is gathering information through direct interaction with users. In this lesson, we'll look at the tools associated with both types.

Before interacting with a target, a hacker should perform passive reconnaissance to gather as much information as possible without alerting the anyone. Gathering information through packet sniffing, eavesdropping, and Open-source intelligence, or OSINT, are the more common passive methods.
Packet sniffing is capturing data packets and analyzing them for useful information. If you're in a public place, you can gather these data packets and use a tool like Wireshark to see if you can find anything useful. Because you're not sending any data, you're essentially a bystander, so this is a passive reconnaissance method.
You need to scan for open wireless networks before you can start sniffing packets. Two common scanning methods are war driving and war flying.
War driving is driving or walking around with a wireless device to look for open vulnerable wireless networks. War flying is the doing the same thing using a drone or another unmanned aerial vehicle.
Eavesdropping is another way you can passively gather information. It can include listening to employee conversations, shoulder surfing, and dumpster diving. People often throw out documents with sensitive information and don't realize it. Holding your nose and sifting through dirty garbage doesn't require any special skills or tools. It's a really easy way for any hacker to get get really valuable information.
Open-source intelligence, or OSINT, is any data collected from publicly available sources. This includes doing web searches on search engines like Google, social media sites such as LinkedIn, and other sources to gather personal identifiable information, or PII.
After a hacker has gained as much information as possible using passive reconnaissance, they'll move on to active reconnaissance.
Active reconnaissance is the process of gathering information by interacting with the target. Because you are directly interacting with the target, you can be discovered.
During this phase, hackers gather additional information that they couldn't get with passive reconnaissance. This includes network information such as IP addresses, sub-domains, and DNS information. They'll also gather system

information such as operating systems, users and passwords, locations of servers, and organizational information that wasn't gathered during passive reconnaissance.
Doing all of this reconnaissance provides a wealth of knowledge on the target. The goal is to understand the target's security, narrow focus for potential attacks, identify vulnerabilities, and create a network map.
Sometimes the line between passive and active reconnaissance can get blurry. Just always remember that and any amount of direct interaction means you're using an active method.
There's a wealth of tools and resources hackers and penetration tester can use to gather all of this information.
One of the first tools a security professional should use in reconnaissance is the OSINT framework. This framework is a collection of resources and tools that are separated by common categories to easily gather all sorts of online information, making the initial reconnaissance process much easier.
theHarvester is a great passive reconnaissance tool that can gather lots of information from public sources, such as search engines, social media sites, and Shodan. There are some options in the program to brute force DNS information, which is active reconnaissance.
Shodan is a very popular search engine for internet-connected devices. Users can search for specific types of devices and locations. You can use this information to see if a target has any online devices without proper security and gather more information about them.
Dnsenum is a program that finds all DNS servers and entries for an organization. This helps you find information such as usernames, computer names, IP addresses, and more. Depending on the settings used, dnsenum can be either passive or active.
Curl and wget are two programs that let you download and upload files. You can use them in the active reconnaissance phase to download an entire website and view its code and resources offline. Because you're actively interacting with the target, these are active reconnaissance tools.
Scanless is a really cool tool for port scanning. It uses exploitation websites to perform port scans on your behalf. This means that you can scan your target anonymously. Even though you're not directly interacting with the target, this's still considered active reconnaissance.
Sn1per is a scanning tool that combines many tools into one program. You can use Sn1per to find all sorts of information, such as DNS, open ports, services, and vulnerabilities. This is definitely an active reconnaissance program.
Finally, we have Nessus. Nessus is a proprietary vulnerability scanner developed by Tenable. You can use Nessus to scan your target for known vulnerabilities that you can exploit to gain access to the target. Nessus has many different options available for scanning, which allows you to narrow your focus.
Using these tools allows you to gather all the information you could want about a person or organization. Network defenders can also use these same tools to discover what information is available to others and take necessary steps to remove or hide anything that shouldn't be accessed.
And that wraps up this lesson. In this video, we compared passive and active reconnaissance techniques. Passive means there is no direct interaction with users, and active means there is direct interaction. We also reviewed some the common tools used in the reconnaissance phase.

6.2.5 Perform Reconnaissance with Nmap (Demo Video)

Transcript:

One of the very first things you do as a penetration tester or ethical hacker is gather information. There are a lot of tools that can help you to do this. Most ethical hackers start with some very basic command line tools. In this demo, we're going to perform some reconnaissance using some of these basic tools. Our target is a domain set up by the Nmap Security Scanner Project and insecure.org. They've set up scanme.nmap.org to help people learn about Nmap and other tools. They authorize students to do scans as long as they're done within reason. Let's close the web browser.

To get started, we're going to go through some reconnaissance steps. First, I just want to make sure that the site is live, so let's ping it. I'll just type, 'ping scanme.nmap.org', press Enter, and I get a response. I'll hit Ctrl+C to stop the ping, and I can confirm that the site is live.
Now let's find the path to our target by performing a traceroute. On Windows, you do that by typing tracert. But we're on our Kali Linux system, so we need to type in 'traceroute scanme.nmap.org' and then Enter. I get over a dozen hops between me and the target. These, down here, aren't responding to the request, but my traceroute still continues. This is normal behavior. Let's clear our screen.

Now, I'm interested in finding the name server information for our target. I'm going to type in 'nslookup scanme.nmap.org' and press Enter. I get the IP addresses for both IP version 4 and version 6 along with the server names.
You can perform a whois search from the command line in Linux. To do that, I'll type in 'whois nmap.org' and press Enter. I'll scroll up, and here, I can see all the information about nmap that's available from whois. I'll clear the screen again.
Next, let's see what happens if we try to make a connection with the target. I know that port 80 is open because we were just at the website. Let's use Netcat to see if we can make a connection to the site on port 80. For that, I'll type in 'nc -v scanme.nmap.org 80' and press Enter. I get a response back, and it looks like I'm connected. Typically, if you want to make sure you're connected, you can type 'help', and you'll get a response. I do get a response. Not only that, I get some information about what sort of server they're running and even the version.
Let's try another. I'll use my up arrow to get back to our last command. I'll change the 80 to a 22 and press Enter. I get a connection again and see that they're running SSH, and I get the version number along with some other information. All right, let's move on. I have to press Ctrl+C to get out of this, and I'll also clear the screen.
You'll get a lot of use out of Nmap as a penetration tester and ethical hacker. We were just using Netcat to make connections to ports. But with 65,535 possible ports, that would take all day. We can use Nmap to do a scan to see what ports are open. To do a port scan, I'll type, 'nmap -sS scanme.nmap.org' and press Enter. The -sS parameter scans the 1,000 most common ports. I get some results back. I know what ports are open. I know the state of the port and what service is running. Now, if I want to continue working with Netcat, I have a list of ports I know are open.
Earlier, we did a ping to see if the target was alive. Let's repeat that now to get the IP address. I'll type 'ping scanme.nmap.org' and press Enter. I'll press Ctrl+C to stop the ping. Now, I want to do a ping sweep to see what other IPs might be associated with scanme.nmap.org. To do a ping sweep, I'll type in 'nmap -sn 45.33.32.1-255' and press Enter. Now I can go through this list and see which other IPs might be associated with scanme.nmap.org.
That's it for this demo. In this demo, we did some basic reconnaissance. First, we used some command line tools to find information about our target. Then we used Netcat to connect to open ports. Finally, we used nmap to perform a basic port scan and a ping sweep.

6.2.6 Reconnaissance Facts

Passive and active reconnaissance provides crucial information that helps penetration testers understand target systems and identify potential vulnerabilities to plan an attack effectively. A combination of active and passive reconnaissance techniques yields the most comprehensive information regarding the target environment during a penetration testing engagement.

This lesson covers the following topics:

- Passive reconnaissance
- Active reconnaissance
- Reconnaissance tools

Passive Reconnaissance

Passive reconnaissance involves gathering information on the target with no direct interaction with that target. Passive reconnaissance aims to gather intelligence on the target environment and identify potential vulnerabilities while generating minimal evidence of their actions. Valuable information can be gathered using passive reconnaissance. The following table shows some of the common passive reconnaissance methods:

Passive Reconnaissance Method	Description
Packet sniffing	Packet sniffing is the process of capturing data packets that are flowing across the network and analyzing them for important information. Modern networks should have

	good protection against network sniffing attacks, but there are occasional circumstances that allow an attacker to gather sensitive information from the data packets. Packet sniffing is most easily performed on open wireless networks. Because the attacker is not sending data or actively interacting with the target, this is considered passive reconnaissance. Scanning for open wireless networks needs to be done before packets can be sniffed. Two common methods are war driving and war flying. • War driving is driving around with a wireless device, looking for open, vulnerable wireless networks. • War flying uses drones or unmanned aerial vehicles to find open wireless networks.
Eavesdropping	Eavesdropping is the act of covertly listening in on a communication between other people. This can include: • Listening to employees' conversations without them knowing. • Shoulder surfing is an eavesdropping technique where the listener obtains passwords or other confidential information by looking over the shoulder of the target as the target logs on or types information. • Dumpster diving, which is also considered eavesdropping. When dumpster diving, the attacker goes through the trash to find important information that may have accidentally been thrown away.
Open-source intelligence (OSINT)	Open-source intelligence is any data that is collected from publicly available sources. The goal is to gather as much personal identifiable information (PII) as possible. This includes information found from resources such as: • Search engines (Google, Bing) • Social media (Facebook, LinkedIn) • Company websites (About sections of websites, company directories) • Media sources (news sites, interviews, articles) • Public government sources (property appraisal sites, public records)
Network traffic analysis	Network traffic analysis involves monitoring network traffic to identify patterns, devices, IP addresses, and potential vulnerabilities without actively generating traffic.

Active Reconnaissance

After an attacker has gained as much information as possible through passive reconnaissance, the next step is the active reconnaissance phase.

Active reconnaissance involves actively probing and interacting with target systems and networks to gather information. Active reconnaissance includes activities that generate network traffic by directly requesting information from target systems. Active reconnaissance aims to discover and obtain information about the target infrastructure, services, and potential vulnerabilities. Common techniques used in active reconnaissance include the following:

- Port scanning — scanning a target network to identify open ports and the services running on them.
- Service enumeration — interacting with identified services to gather information about their versions, configurations, and potential vulnerabilities.
- OS fingerprinting — attempting to identify the operating system running on target machines by analyzing network responses and behavior.
- DNS enumeration — gathering information about the target's DNS infrastructure, such as domain names, subdomains, and IP addresses.
- Web application crawling — exploring web applications to identify pages, directories, and potential vulnerabilities.

Performing reconnaissance provides the attacker with the information needed to perform a successful attack on the target. The goal is to know and understand the following information about the target:

- Security posture (this includes both network and physical security)
- How to narrow the focus for attack
- Potential vulnerabilities
- How to best create a network map

Reconnaissance Tools

There are many tools and resources available to assist in the reconnaissance phase. The table below covers some of the popular tools used:

Reconnaissance Tool	Description
OSINT framework	The OSINT framework is a collection of resources and tools that are separated by common categories. The OSINT Framework makes it easy to gather all sorts of information, making the initial reconnaissance process much more efficient. Documentation can be found at https://osintframework.com/
theHarvester	theHarvester is a passive reconnaissance tool that is used to gather information from a variety of public sources. The tool gathers emails, names, subdomains, IPs, and URLs using multiple public data sources. These sources include search engines, social media sites, and Shodan. theHarvester does have some options, such as brute-forcing DNS and taking screenshots, that would fall under active reconnaissance.
Shodan	Shodan is a popular search engine for internet-connected devices. Users are able to search for specific types of devices and locations. This information can be used to see if a target has any online devices without proper security.
Dnsenum	Dnsenum is a program that performs DNS enumeration and can find the DNS servers and entries for an organization. This information can help find other information such as usernames, computer names, IP addresses, and more.

Curl and wget	Curl and wget are two common command line programs that can be used to download or upload files. An example of using these tools is to download an entire website for offline analysis. Because these tools actively engage with the target, they are considered active reconnaissance tools.
Scanless	Scanless is used for port scanning. Instead of scanning ports from the hacker machine, scanless uses exploitation websites to perform port scans. This means the attacker is able to maintain anonymity while scanning the target.
Sn1per	Sn1per is an automated scanner that can be used to enumerate and scan for vulnerabilities. Sn1per combines the functions of many tools and can be used to find information such as DNS information, open ports, running services, and more.
Nessus	Nessus is a proprietary vulnerability scanner that was developed by Tenable. Nessus can be used to scan the target for any known vulnerabilities, which can be exploited to gain access to the target.

Selecting the right tool allows the attacker to gain the necessary information on the target. Network defenders can also use these tools to discover what information is out there and take the necessary steps to remove or hide anything that should not be available.

6.2.7 Practice Questions (Section Quiz)

q_netmon_dig_secp8

Which of the following tools can be used to view and modify DNS server information in Linux?

Answers:

- tracert
- ***dig**
- route
- netstat

Explanation:

The **dig** command is used to view and modify DNS settings. These tools can be used to look up DNS server information and give IP addresses and domain names for a network server.

The **tracert** command shows the path a packet takes to reach its destination. This is not the best tool for checking connectivity between two network devices.

The **route** command is used in both Windows and Linux to show the routing table and to make manual changes to it.

The **netstat** command is used to display a variety of network statistics in both Windows and Linux. This command is not used to look up DNS server information.

q_netmon_endpoint_hardening_secp8

In the context of network monitoring, which of the following is crucial for enforcing and maintaining the security measures put in place during the hardening process?

Answers:

- ***Endpoint hardening**
- Top talkers
- Packet routing
- IP scanning

Explanation:

Endpoint hardening is the correct answer. It refers to the process of securing individual devices on a network (endpoints) against threats. Network monitoring plays a vital role in endpoint hardening as it helps to enforce and maintain the security measures put in place during the hardening process. It can detect changes that weaken the hardened configuration and alert analysts of the change, which may indicate a breach.

Top talkers refers to the computers that send the most data, either from your network or into your network. While monitoring these can help identify potential network issues, it is not directly related to the enforcement and maintenance of security measures.

Packet routing refers to the path a packet takes to reach its destination. While this is an important aspect of network monitoring, it does not directly relate to the enforcement and maintenance of security measures.

IP scanning is a process that allows a network administrator to scan the entire network to find all connected devices and their IP addresses. While this is a useful tool in network monitoring, it does not directly enforce or maintain security measures.

q_netmon_hping_secp8

A tech startup, TechPioneers Inc., is looking to improve their network monitoring capabilities.

The company operates primarily on Linux-based systems and requires a tool that can not only check connectivity but also analyze targets to gather information. The tool should be capable of sending ICMP, TCP, UDP, and RAW-IP packets.

As a network administrator, which of the following tools would you recommend as the BEST solution for TechPioneers Inc.?

Answers:

- Ping
- Tracert/Traceroute
- ***Hping**
- Netstat

Explanation:

Hping is the best solution for TechPioneers Inc. Hping can check connectivity and also analyze the target to gather information. It can send ICMP, TCP, UDP, and RAW-IP packets. Although it is primarily designed for Linux, it can also be installed in Windows, making it a versatile choice for diverse network environments.

While ping is a useful tool for checking the connectivity between two network devices by sending ICMP packets and waiting for a response, it does not have the capability to analyze targets for gathering information or send TCP, UDP, and RAW-IP packets. Therefore, it is not the best solution for TechPioneers Inc.

Tracert/Traceroute is a tool that shows the path a packet takes to reach its destination, identifying each device the packet passes through. However, it does not have the capability to analyze targets for gathering information or send TCP, UDP, and RAW-IP packets. Therefore, it is not the best solution for TechPioneers Inc.

Netstat is a command-line tool that displays network statistics, including connections for different protocols, open ports, and running programs. However, it does not have the capability to analyze targets for gathering information or send TCP, UDP, and RAW-IP packets. Therefore, it is not the best solution for TechPioneers Inc.

q_netmon_nmap_secp8

You want to identify all devices on a network along with a list of open ports on those devices. You want the results displayed in a graphical diagram.

Which tool should you use?

Answers:

- Ping scanner
- OVAL
- Port scanner
- ***Network mapper**

Explanation:

A network mapper is a tool that can discover devices on a network and show those devices in a graphical representation. Network mappers typically use a ping scan to discover devices and a port scanner to identify open ports on those devices.

A ping scanner only identifies devices on a network, but does not probe for open ports.

A port scanner finds open ports, but it might not display devices in a graphical representation.

Open Vulnerability and Assessment Language (OVAL) is an international standard for testing, analyzing, and reporting the security vulnerabilities of a system.

q_netmon_ping_secp8

You need to check network connectivity from your computer to a remote computer.

Which of the following tools would be the BEST option to use?

Answers:

- tracert
- nmap
- ***ping**
- route

Explanation:

The **ping** command is used to perform a connection test between two network devices. It works by sending ICMP packets to a specified device on a network and waiting for a response. This shows if there is a connection issue or not.

The **tracert** command shows the path a packet takes to reach its destination. This is not the best tool to check for connectivity between two network devices.

The **nmap** utility is a network security scanner. Use **nmap** to scan an entire network or specific IP addresses to discover all sorts of information. This is not the best tool to check for connectivity between two network devices.

The **route** command is used in both Windows and Linux to show the routing table and to make manual changes to it.

q_recon_active_01_secp8

A company hires a security analyst to perform a penetration test on its network. During the process, the analyst plans to use various reconnaissance techniques to collect information about the target system.

In which of these reconnaissance methods does the security analyst directly interact with the target system?

Answers:

- ***Active**
- Passive
- Open-source intelligence (OSINT)
- Social engineering

Explanation:

Active reconnaissance involves probing and interacting with targeted systems to gather information about them.

Passive reconnaissance focuses on collecting publicly available data and passively observing network traffic without directly interacting with the target systems.

Open-source intelligence gathering is a passive reconnaissance technique that involves collecting publicly available information from various sources like search engines, social media, public databases, and websites.

Social engineering involves gathering information by manipulating people into revealing confidential information. It is part of passive reconnaissance since it does not involve direct interaction with the target systems.

q_recon_active_02_secp8

As a cybersecurity analyst, you are tasked with performing active reconnaissance on a potential client's network to identify vulnerabilities. You have already completed the passive reconnaissance phase.

Which of the following steps would you take next, and why?

Answers:

- Start by launching a denial-of-service (DoS) attack to test the network's resilience.
- ***Begin with port scanning to identify open ports and the services running on them.**
- Immediately report to the client that their network is secure based on the passive reconnaissance results.
- Use social engineering techniques to trick employees into revealing sensitive information.

Explanation:

Beginning with port scanning is the correct answer. Port scanning is a common technique used in active reconnaissance. It involves scanning a target network to identify open ports and the services running on them. This information can help identify potential vulnerabilities and areas for further investigation.

Launching a DoS attack during the reconnaissance phase is not ethical or legal. It could also potentially harm the client's network and disrupt their operations. Active reconnaissance should be non-disruptive and focused on gathering information, not causing harm.

While passive reconnaissance can provide valuable information, it does not provide a complete picture of the network's security. Active reconnaissance is necessary to further probe the network and identify potential vulnerabilities that were not apparent during the passive reconnaissance phase.

Social engineering techniques are not part of active reconnaissance. They involve manipulating individuals into revealing sensitive information, which is not ethical and could potentially be illegal. Active reconnaissance should focus on technical methods of gathering information about the network.

q_recon_nessus_secp8

You want to use a tool to scan a system for vulnerabilities, including open ports, running services, and missing patches.

Which tool should you use?

Answers:

- ***Nessus**
- LC4
- Wireshark
- OVAL

Explanation:

A vulnerability scanner is a software program that searches an application, computer, or network for weaknesses. These weaknesses could be things such as open ports, running applications or services, missing critical patches, default user accounts that have not been disabled, and default or blank passwords. Vulnerability scanning tools include Nessus, Retina Vulnerability Assessment Scanner, and Microsoft Baseline Security Analyzer (MBSA).

Wireshark is a protocol analyzer.

LC4 is a password-cracking tool that you can use to identify weak passwords.

Open Vulnerability and Assessment Language (OVAL) is an international standard for testing, analyzing, and reporting the security vulnerabilities of a system.

q_recon_osint_01_secp8

Gathering as much personally identifiable information (PII) on a target as possible is a goal of which reconnaissance method?

Answers:

- Active

- ***OSINT**
- Packet sniffing
- Passive

Explanation:

Open-source intelligence is any data that is collected from publicly available sources. The goal is to gather as much personally identifiable information (PII) as possible on the target.

Dumpster diving is when an attacker goes through the trash to find important information that may have accidentally been thrown away.

Active reconnaissance is the process of gathering information by interacting with the target in some manner.

Packet sniffing is the process of capturing data packets that are flowing across a network and analyzing them for important information.

q_recon_osint_02_secp8

An IT administrator has reviewed security policies and best practices on well-known IT bulletin boards. During this reading, the admin became aware of several new vulnerability exploits.

What type of information is this?

Answers:

- ***Open-source intelligence (OSINT)**
- Information-sharing organizations
- Cyber threat intelligence
- Threat feeds

Explanation:

Open-source intelligence (OSINT) describes collecting and analyzing publicly available information and using it to support decision-making. OSINT identifies vulnerabilities and threat information by gathering data from many sources such as blogs, forums, social media platforms, and even the dark web.

Information-sharing organizations are groups composed of businesses, government entities, and academic institutions. Each member of an organization benefits from sharing information with the group members.

Cyber threat intelligence is investigating, collecting, analyzing, and disseminating information about emerging threats and threat sources.

Threat feeds are signatures and pattern-matching rules supplied to analysis platforms as an automated feed. Companies respond swifter to emergent threats, as threat feeds provide real-time information.

q_recon_osint_03_secp8

A threat actor will use basic internet research to gather enough information about a local college to determine attack vectors.

Which of the following BEST describes passive reconnaissance that involves little physical work to accomplish the task?

Answers:

- ***OSINT**
- Bug bounty
- Service enumeration
- OS Footprinting

Explanation:

Open-source intelligence (OSINT) is any intelligence derived from publicly available information. The public information can include domains, IP address ranges, employees, and other data that will identify attack vectors.

Software vendors operate bug bounty programs where they give rewards for reporting vulnerabilities on their applications or systems.

Service enumeration is an active reconnaissance activity where people interact with identified services to gather information about their versions, configurations, and potential vulnerabilities.

Footprinting means scanning for hosts, IP ranges, and routes between networks to map out the structure of the target network.

q_recon_passive_01_secp8

Which type of reconnaissance is associated with dumpster diving?

Answers:

- Active
- OSINT
- Packet sniffing
- ***Passive**

Explanation:

Dumpster diving is when an attacker goes through the trash to find important information that may have accidentally been thrown away. Because there is no direct interaction with the target, dumpster diving is a form of passive reconnaissance.

Active reconnaissance is the process of gathering information by interacting with the target in some manner. Dumpster diving does not fall under this category.

Open-source intelligence (OSINT) is any data that is collected from publicly available sources. Dumpster diving does not fall under this category.

Packet sniffing is the process of capturing data packets that are flowing across a network and analyzing them for important information. Dumpster diving does not fall under this category.

q_recon_passive_02_secp8

Which passive reconnaissance tool is used to gather information from a variety of public sources?

Answers:

- ***theHarvester**
- Packet sniffing
- Shodan
- scanless

Explanation:

theHarvester is a passive reconnaissance tool that is used to gather information from a variety of public sources. This tool gathers emails, names, subdomains, IPs, and URLs using multiple public data sources. These include search engines, social media sites, and Shodan.

Packet sniffing is the process of capturing data packets that are flowing across a network and analyzing them for important information.

Shodan is a popular search engine for internet-connected devices. Users can search for specific types of devices and locations.

Use scanless for port scanning. Instead of an attacker scanning ports from their own machine, scanless uses exploitation websites to perform port scans on their behalf.

q_recon_recon_secp8

Which of the following tools can be used to see if a target has any online IoT devices without proper security?

Answers:

- theHarvester
- Packet sniffing
- ***Shodan**
- scanless

Explanation:

Shodan is a popular search engine for internet-connected devices. Users can search for specific types of devices and locations. This information can be used to see if a target has any online devices without proper security.

theHarvester is a passive reconnaissance tool that is used to gather information from a variety of public sources.

Packet sniffing is the process of capturing data packets that are flowing across the network and analyzing them for important information.

Use scanless for port scanning. Instead of the attacker scanning ports from their own machine, scanless uses exploitation websites to perform port scans on their behalf.

q_recon_theharvester_secp8

You are a cybersecurity analyst tasked with performing passive reconnaissance on a potential client's network.

You need to gather information from a variety of public sources including emails, names, subdomains, IPs, and URLs.

Which of the following tools would be most appropriate for this task?

Answers:

- Shodan
- ***theHarvester**
- Dnsenum
- OSINT framework

Explanation:

theHarvester is the correct answer. This tool is specifically designed for passive reconnaissance and can gather a wide range of information from various public sources including emails, names, subdomains, IPs, and URLs. It uses multiple public data sources including search engines, social media sites, and Shodan, making it the most appropriate tool for this task.

While Shodan is a powerful tool for finding internet-connected devices, it is not specifically designed for gathering a wide range of information from various public sources such as emails, names, subdomains, IPs, and URLs.

While Dnsenum is a useful tool for DNS enumeration, it is not as comprehensive as theHarvester for gathering a wide range of information from various public sources.

While the OSINT framework is a collection of resources and tools for open-source intelligence, it does not have the specific functionality of gathering emails, names, subdomains, IPs, and URLs from various public sources like theHarvester does.

q_recon_war_driving_secp8

Which of the following is known as the process of walking around an office building with an 802.11 signal detector.

Answers:

- War dialing
- Daemon dialing
- Driver signing
- ***War driving**

Explanation:

War driving is the act of searching for wireless networks (802.11) using a signal detector or a network client (such as a PDA or notebook). While the phrase war driving originated from the action of driving around a city searching for wireless networks, the name currently applies to any method of searching for wireless networks, including walking around.

War dialing and daemon dialing are both the act of dialing phone numbers in search of an answering modem. Often, war/daemon dialing calls all of the phone numbers in an area code or a prefix range in search of active modems.

Driver signing is a method of signing device drivers in an attempt to verify the source and quality of installed drivers. However, signing a device driver only indicates its source. Signing does not guarantee the reliability, stability, quality, or compatibility of a device driver.

6.3 Intrusion Detection

As you study this section, answer the following questions:

- What is the difference between an IDS and IPS?
- Which component gathers data from source devices?

- Why is a false negative the worst possible action by an IDS?
- Which detection method causes more false negatives?
- What is the difference between a host-based and network-based IDS/IPS implementation method?

In this section, you will learn to:

- Implement intrusion detection and prevention.

The key terms for this section include:

Term	Definition
Intrusion detection system (IDS)	Device or software that monitors, logs, and detects security breaches, but takes no action to stop or prevent the attack.
Intrusion prevention system (IPS)	Device that monitors, logs, detects, and can also react to stop or prevent security breaches.
Sensor	IDS component that passes data from the source to the analyzer.
Engine	IDS component that analyzes sensor data and events, generates alerts, and logs all activity.
Signature-based detection	Also referred to as pattern matching, dictionary recognition, or misuse-detection (MD-IDS). This detection method looks for patterns in network traffic and compares them to known attack patterns called signatures.
Heuristic-based detection	Also referred to as behavior, anomaly, or statistical-based detection. This detection method first defines a baseline of normal network traffic and then monitors traffic looking for anything that falls outside that baseline.

This section helps you prepare for the following certification exam objectives:

Exam	Objective

CompTIA Security+ SY0-701	2.5 Explain the purpose of mitigation techniques used to secure the enterprise.
	• Hardening techniques
	  ○ Host-based intrusion prevention system (HIPS)
	
	3.2 Given a scenario, apply security principles to secure enterprise infrastructure.
	• Infrastructure considerations
	  ○ Device attribute
	  ▪ Inline vs. tap/monitor

	○ Network appliances ▪ Intrusion prevention system (IPS)/intrusion detection system (IDS) ▪ Sensors 4.3 Explain various activities associated with vulnerability management. • Analysis ○ False positive ○ False negative 4.5 Given a scenario, modify enterprise capabilities to enhance security. • IDS/IPS ○ Trends ○ Signatures • User behavior analytics 5.6 Given a scenario, implement security awareness practices. • Anomalous behavior recognition ○ Unexpected
TestOut Security Pro	5.2 Assessment techniques 5.2.1 Implement intrusion detection

6.3.1 Intrusion Detection (Lesson Video)

Transcript:

The first step in defending our network against unauthorized access is knowing if someone is attempting to gain access. To assist network defenders in this task, we can implement network intrusion detection or network intrusion prevention systems. In this lesson, we'll look at the differences, detection methods, and implementation of these systems.

To better understand the differences between an intrusion detection and intrusion prevention system, lets take a look at what each of them do.
An intrusion detection system, or IDS, is used to monitor and detect unauthorized access. It doesn't try to stop an attack or prevent traffic; it just monitors data packets and creates logs. An IDS can be either a software program or a hardware device.
Similar to an IDS is an intrusion prevention system, or IPS. Not only does the IPS monitor network traffic, it also works to block unauthorized and suspicious packets from entering the network.
No solution is perfect, and that's why we should always implement security-in-depth and use both detection and prevention systems. Even with an IPS, malicious packets may still find their way into the network. The IDS can serve as a backup and alert us that something suspicious may be going on and record it for us. This information will be extremely valuable after the attack so that we can figure out exactly what happened and what the damage is.
Now that we understand what an IDS and IPS are, lets take a look at how they work.
Both IDS and IPS systems monitor data packets for suspicious traffic. They do vary slightly in how they accomplish this, but both systems use generally the same methods. For simplicity's sake we'll talk about the IDS systems, but understand that all of this can apply to both unless otherwise specified.

This first and most common method is signature-based detection. This type of IDS is sometimes called a misuse-detection IDS. It attempts to match the known traffic patterns of specific network attacks. Similar to how viruses have a unique fingerprint that antivirus programs use to detect them, malicious packets also have a unique fingerprint that the IDS can use to identify them with.
The other detection method is heuristic, or behavior-based detection, sometimes referred to as statistical anomaly-based detection. With this type of detection, you set up a baseline of regular network activity and the IDS determines if activity is outside the norm. The biggest issue with this method is that a larger number of false positives are likely to be generated.
No matter the detection method being used, an IDS can either be a host-based or network-based IDS.
A host-based IDS is software installed on the host system. Host-based IDSs are better at detecting attacks unique to the services and applications on that system than network-based IDSs. A host-based IDS also monitors local files for suspicious activity, which is something a network-based IDS can't do. The problem with host-based IDSs is that software must be installed on each system you want to protect. This can lead to excessive administrative effort. Also, if a system is compromised, the log reports on that system become unreliable because the attacker may have modified the log files.
The other option is to install the IDS on the network itself. This is a physical device that monitors network traffic in real time. We have two options on where to install a network IDS: inline or out of band.
Because an IDS is a passive device that simply monitors packets, they're generally installed as out-of-band devices. All this means is that the device is installed outside the flow of traffic. It's usually connected with a network tap, like a switch, which allows it to monitor traffic without being in the way.
An IPS on the other hand is an active device that's usually installed inline, or in the flow of traffic. All data goes through the IPS, where it's checked out and either allowed to pass through or stopped.
Regardless of whether the device is inline or out of band, it can be installed in front of or behind the firewall. Generally, an IDS or IPS should be installed behind the firewall as this uses less resources.
That'll wrap things up for this lesson. In this lesson, we looked at intrusion detection and intrusion prevention systems. The biggest difference between the two is that an IDS is a passive monitoring device and an IPS is an active prevention device. We also looked at the common detection methods that both use, which are signature-based detection and heuristic, or behavior-based, detection. Finally, we looked at how to install these devices on a network. IDSs should be installed out of band and IPSs should be inline.

6.3.2 IDS Facts

The first step in defending a network against unauthorized access is knowing that someone is gaining access. An intrusion detection system (IDS) is a special network device that can detect attacks and suspicious activity. An active IDS is known as an intrusion prevention system (IPS).

This lesson covers the following topics:

- Differences between an IDS and IPS
- Detection methods
- Device implementation
- Trend Analysis

Differences between an IDS and IPS

The table below shows the differences between an IDS and an IPS:

IDS	IPS
A passive IDS monitors, logs, and detects security breaches but takes no action to stop or prevent the attack. A passive IDS:	An active IDS, also called an IPS, performs the functions of an IDS but can

• Can send an alert, but this requires the security administrator to interpret the degree of the threat and respond accordingly. • Cannot be detected on the network because it takes no detectable actions.	also react when security breaches occur. An IPS: • Can automate responses to malicious or suspicious traffic. • Can terminate sessions (using the **TCP-RST** command) or restart other processes on the system. • Performs behaviors that can be seen by anyone watching the network. Usually, these actions are necessary to block malicious activities or discover the identity of an intruder. Updating filters and performing reverse lookups are common behaviors of an

	active IDS.

Using both of these devices in a network provides the best network detection and protection. If a malicious packet makes it past the IPS, the IDS serves as a backup and alerts the security operations team.

The IDS also records and logs everything (this can be viewed in the follow-up).

The steps an IDS/IPS takes when monitoring traffic are:

- A sensor passes data from the source to the analyzer.
- The engine, or analyzer, analyzes the sensor data and events, generates alerts, and logs all activity. An *alert* is a message indicating an event of interest (such as a possible attack)
- The IDS/IPS labels traffic based on its interpretation of whether or not the traffic poses a threat, as described in the following table.

State	Description
Positive	A positive traffic assessment means that the system detected an attack, the appropriate alarms and notifications were generated, or the correct actions were performed to prevent or stop the attack.
False positive	A false positive traffic assessment means that the system identified harmless traffic as offensive and generated an alarm or stopped the traffic.
Negative	A negative traffic assessment means that the system deemed the traffic harmless and let it pass.
False negative	A false negative traffic assessment means that harmful traffic was allowed to pass without any alerts being generated or any actions being taken to prevent or stop it. This is the worst possible scenario.

Detection Methods

Both systems monitor data packets for malicious or unauthorized traffic. The table below shows the different methods they can use to distinguish attacks and threats from normal traffic:

Detection Method	Description
Signature-based	Signature-based detection also referred to as pattern matching, dictionary recognition, or misuse-detection (MD-IDS), looks for patterns in network traffic and compares them to known attack patterns called signatures. Similar to how viruses have a unique fingerprint that antivirus programs use to detect their presence, malicious packets have a unique fingerprint that the IDS can use to do the same. These fingerprints are referred to as signatures. • Signatures are written and updated by the IDS vendors.

	• Signature-based detection cannot detect unknown attacks; it can only detect attacks identified by published signature files. For this reason, it is important to update signature files on a regular basis. Commercial software requires a paid-for subscription to obtain the updates. It is important to configure software to update only from valid repositories, ideally using a secure connection method such as HTTPS. • Signature-based detection usually causes more false negatives than heuristic-based detection.
Heuristic-based	Heuristic-based detection, also referred to as behavior, anomaly, or statistical-based detection, first defines a baseline of normal network traffic and then monitors it. It looks for anything that falls outside that baseline. • Clipping levels, or thresholds, are defined and used to identify deviations from the baseline. • When the threshold is reached, an alert is generated, or action is taken. • Heuristic-based systems can recognize and respond to some unknown attacks (attacks that do not have a corresponding signature file). • This detection method usually causes more false positives than signature-based detection.

Device Implementation

An IDS/IPS can be implemented as a host-based or network-based device. The table below describes each implementation:

Implementation Method	Description
Host-based	A *host-based* IDS (HIDS) is a program installed on the host system itself that monitors all traffic coming into the host. A host-based IDS: • Is used to detect attacks that are unique to the services and applications on that system. It can monitor application activity and modifications as well as local system files, logon audit files, and kernel audit files. • Is typically unaware of other devices on the network but can be detected and could be the target of an attack itself. • May rely on auditing and logging capabilities of the operating system. • Can analyze encrypted traffic (because services running on the host decrypt the traffic). Antivirus software is the most common form of host-based IDS. One issue with host-based IDSs is that the software must be installed and configured on each system being protected. This can lead to excessive administrative effort. Also, if the host system is compromised, the log reports on that system become unreliable because the attacker may have modified the log files.

Network-based	A *network-based IDS* (NIDS) is a dedicated device installed on the network. It analyzes all traffic on the network in real-time. There are two options when installing an NIDS:
	• The first option is to install the NIDS out of the band. This means it is installed outside the flow of traffic.
	  ○ The IDS is usually connected with a network tap, such as a switch. This allows it to monitor network traffic without being in the way.
	• The other option is to install the NIDS as an *inline* device. This means it is installed in the flow of traffic, and all traffic goes through the NIDS. It is then analyzed and either allowed to continue or is stopped.
	
	Some other things to be aware of when implementing an NIDS are:
	• An NIDS is typically unaware of individual hosts on the network. It cannot be detected by attacking systems.
	• An NIDS is particularly well suited for detecting and blocking port scanning and DoS attacks.
	• An NIDS is unable to analyze encrypted traffic.
	• An NIDS should be placed at all critical junctions within a network, including backbones and critical choke points, such as:
	  ○ Inside the DMZ.
	  ○ Between the firewall and the internal LAN.
	  ○ Near any critical information assets.
	  ○ If using a switch on the network, the NIDS must be placed on a special port called a *spanning* or *diagnostic* port that directly connects to the backbone of the switch. This way, the NIDS can see all traffic on that segment.
	• A control center should be set up to receive all IDS data. This is where all decision-making should take place regarding NIDS communications.
	• An application-aware NIDS can analyze network packets to detect malicious payloads targeted at Application layer services (such as a web server).

Trend Analysis

Trend analysis is a critical aspect of managing intrusion detection systems (IDS) and intrusion prevention systems (IPS) as it aids in understanding an environment over time, helping to identify patterns, anomalies, and potential threats. Security analysts can identify patterns and trends that indicate ongoing or growing threats by tracking events and alerts. For example, an increase in alerts related to a specific attack may suggest that a network is being targeted for attack or that a vulnerability is being actively exploited. Trending can also help in tuning IDS/IPS systems. Over time, security analysts can identify false positives or unnecessary alerts that appear frequently. These alerts can be tuned down so analysts can focus on more important alerts.

Trending data can contribute to operational security strategies by identifying common threats and frequently targeted systems. This approach highlights areas of weakness that need attention, either through changes in security policy or investment in additional security tools and training.

6.3.3 Implement Intrusion Detection and Prevention (Demo Video)

Transcript:

Intrusion detection and prevention is an important task that is required to protect todays networks. In this demonstration, we'll configured intrusion detection and prevention using Snort on a pfSense security appliance.

There are several products available that can do both intrusion detection and intrusion prevention. Some cost money and some are free.
One of the most popular products is Snort. Snort is a free, open source network intrusion detection system (IDS) and intrusion prevention system (IPS).
Although Snort is open source and free, it does have some paid plans that you can subscribe to and receive updates to rules faster. In this demo, we'll configure Snort on our pfSense security appliance.
Before we configure Snort, let's quickly look at the website. As we scroll down, you see that you can manually download Snort for various operating systems and distributions. Snort is available for Fedora, Centos, FreeBSD and Windows.
In the second step, you must get what is called an Oinkcode. We will do that in a minute but let's keep scrolling down this page. Step 3 is to get updates. We'll cover that later in the demo.
Now as a review what we just talked about, Snort is an open source intrusion prevention system capable of real-time traffic analysis and packet logging.
Snort is the most widely deployed IPS in the world. There have been over 5 million downloads and over 600 thousand registered users.
To use Snort, you must first get an Oinkcode. We'll go to our account. Here is a link that says Oinkcode. We already have a code generated, so we can proceed. We will use the Oinkcode later.
Now let's go to pfSense and install Snort.
We've already logged into pfSense and we're on the Dashboard. Installing Snort on pfSense is quite easy. It is done with the Package Manager that is located under the System tab. Once on the Package Manager page, you click Available Packages.
Now let's do a search for â€˜Snort'. We have one result, so we'll come down and click the Install link. Now you can make sure you have the right package. We do; so let's click Confirm to start the installation.
Now we wait for a few minutes while Snort is installed. When it does, the color changes from red to green and it says that the installation successfully completed. Down here on the bottom, a message says "Success".
Now that Snort is installed, we need to set it up. Let's do that by going to Services and then down to Snort. Be aware that this menu item for Snort was not there until we installed it. If you don't have this menu, Snort probably is not installed.
We will start by going to Global Settings. Under Snort Subscriber Rules, we check the Enable Snort VRT box. VRT is an acronym for Vulnerability Research Team.
Below that, next to Snort Oinkmaster Code, we paste in the code. Remember, we got the Oinkcode from the Snort website that we were at in the beginning of the demo. We copied the code to the clipboard and will use a keyboard shortcut to paste it in here.
Next, we Enable Snort GPLv2. The Community Snort Rules fall under the GNU General Public License Version 2, which encourages the development and distribution of open source software. This ruleset is 30 days behind the Snort Subscriber Rule Set. It does not contain zero-day threats under the limited provision of the Snort Subscriber Rule Set License.
Now let's check Enable ET Open (ET is the acronym for Emerging Threats). This downloads the Emerging Threats Open rules. The ET Open Ruleset is an anti-malware IDS/IPS ruleset that enables users with cost constraints to enhance their existing network-based malware detection.
We do not pay for the Emerging Threat Pro rules, so we won't check that box.
Let's skip down here under Sourcefire OpenAppID Detectors. Let's check the Enable OpenAppID box. Below that, check the box next to Enable RULES Open AppID. OpenAppID is an application-focused detection language and processing module for Snort. When you use OpenAppID with pfSense, the system can successfully detect (if configured to do so) and block over 2600 different services like Facebook, Netflix, Twitter, and Reddit.
For our Rules Update Settings, we set the Update Interval to 1 Day. For our Update time, we set it to 2:00 AM. Let's check the Hide Deprecated Rules Categories box. This removes old and outdated rules.
Under General Settings > Remove Blocked hosts Interval, we change that to 1 Hour. Now you might think that we should block hosts forever if they are malicious, but the problem is that often these are coming from spoofed IP addresses or from addresses that may be used by legitimate users very soon. So, we will block only for 1 hour.
We'll check the box for Startup/Shutdown Logging. We want to know who and when Snort is being started and stopped by.
That wraps up everything for this page. We'll click Save.
Now that we have the rules figured out, we need to assign these rules to the WAN interface. We'll go to the Snort Interfaces tab. Then come down here to the right and click the Add link.

Under General Settings, we want to make sure that Enable Interface is checked. We see that it is. Make sure you have WAN selected under Interface. This is the traffic we want to inspect. For Description, we enter WAN. We want to keep it obvious and simple here.
Under Alert Settings, we check the box to Send Alerts to System Log. This will send alerts to the firewall log.
We check the Block Offenders box. If an offender creates a Snort alert, they will be blocked. For the IP to Block, we block the Source IP address.
There is nothing more we want to do here. We'll come down and click Save.
Now we want to check the box to enable the WAN interface. Under Snort Status, click Runto start Snort.
That's it for this demo. In this demo we configured intrusion detection and prevention using Snort on our pfSense security appliance.

6.3.4 Implement Intrusion Prevention (Simulation)

Scenario

You work as the IT security administrator for a small corporate network. In an effort to protect your network against security threats and hackers, you have added Snort to pfSense. With Snort already installed, you need to configure rules and settings and then assign Snort to the desired interface.

In this lab, your task is to use pfSense's Snort to complete the following:

Sign in to pfSense using the following:

- Username: **admin**
- Password: **P@ssw0rd** (zero)

- Enable the downloading of the following:
  - Snort free registered User rules
    - Oinkmaster Code: **359d00c0e75a37a4dbd70757745c5c5dg85aa**
  - Snort GPLv2 Community rules
  - Emerging Threats Open rules
  - Sourcefire OpenAppID detectors
  - APPID Open rules
- Configure rule updates to happen once a day at 1:00 a.m.
  - Hide any deprecated rules.
- Block offending hosts for 1 hour.
- Send all alerts to the system log when the Snort starts and stops.
- Assign Snort to the WAN interface using a description of **WANSnort** .
  - Include:
    - Sending alerts to the system log
    - Automatically blocking hosts that generate a Snort alert
- Start Snort on the WAN interface.

Explanation

Complete this lab as follows:

1. Sign in to the pfSense management console.
   a. In the Username field, enter **admin** .
   b. In the Password field, enter **P@ssw0rd** (zero).
   c. Select **SIGN IN** or press **Enter** .
2. Access the Snort Global Settings.
   a. From the pfSense menu bar, select **Services** > **Snort** .

b. Under the Services breadcrumb, select **Global Settings** .

3. Configure the required rules to be downloaded.
    a. Select **Enable Snort VRT** .
    b. In the *Sort Oinkmaster Code* field, enter **359d00c0e75a37a4dbd70757745c5c5dg85aa** . You can copy and paste this from the scenario.
    c. Select **Enable Snort GPLv2** .
    d. Select **Enable ET Open** .
4. Configure the Sourcefire OpenAppID Detectors to be downloaded.
    a. Under Sourcefire OpenAppID Detectors, select **Enable OpenAppID** .
    b. Select **Enable RULES OpenAppID** .
5. Configure when and how often the rules will be updated.
    a. Under Rules Update Settings, use the Update Interval drop-down menu to select **1 Day** .
    b. For Update Start Time, change to **01:00** .
    c. Select **Hide Deprecated Rules Categories** .
6. Configure Snort General Settings.
    a. Under General Settings, use the Remove Blocked Hosts Interval drop-down menu to select **1 HOUR** .
    b. Select **Startup/Shutdown Logging** .
    c. Select **Save** .
7. Configure the Snort Interface settings for the WAN interface.
    a. Under the Services breadcrumb, select **Snort Interfaces** and then select **Add** .
    b. Under General Settings, make sure **Enable interface** is selected.
    c. For Interface, use the drop-down menu to select **WAN (CorpNet_pfSense_L port 1)** .
    d. For Description, use **WANSnort** .
    e. Under Alert Settings, select **Send Alerts to System Log** .
    f. Select **Block Offenders** .
    g. Scroll to the bottom and select **Save** .
8. Start Snort on the WAN interface.
    a. Under the Snort Status column, select the **arrow** .
    b. Wait for a checkmark to appear, indicating that Snort was started successfully.

6.3.5 Practice Questions (Section Quiz)

q_ids_active_passive_secp8

An organization in the education sector plans to implement an Intrusion Detection System (IDS) with strategically placed sensors as part of its network infrastructure redesign to improve enterprise security.

The IT manager also considers implementing an Intrusion Prevention System (IPS) and deliberates over active versus passive modes.

Which statement BEST describes the implications of choosing an active IPS over a passive IDS?

Answers:

- ***An active IPS can block malicious traffic but may introduce latency, while a passive IDS avoids latency.**
- An active IPS can only detect and alert on malicious traffic, while a passive IDS can block such traffic.
- Both an active IPS and a passive IDS can block malicious traffic, but the IPS causes more latency.
- Both an active IPS and a passive IDS can only detect and alert on malicious traffic and cause latency.

Explanation:

An active IPS can block malicious traffic but may introduce some latency into the network traffic. A passive IDS cannot block traffic. It can only detect and alert malicious traffic and does not cause latency.

It is inaccurate to state that an active IPS can only detect malicious traffic, and a passive IDS can block such traffic. In reality, it's the other way around.

Active IDS can block malicious traffic, while passive IDS cannot block malicious traffic.

An active IPS can do more than detect and alert malicious traffic, it can also block such traffic.

q_ids_analysis_engine_secp8

A small company recently installed an intrusion detection system (IDS).

What is the purpose of the analysis engine in the IDS?

Answers:

- To capture network traffic
- ***To interpret and scan captured traffic for suspicious activity**
- To generate incident reports for security analysts
- To update the signatures and rules for attack patterns

Explanation:

An IDS's analysis engine scans and interprets the captured traffic to identify suspicious activity, classify events (e.g., ignore, log, alert, or block), and generate incident reports.

The sensor, not the analysis engine, is responsible for capturing network traffic in an IDS.

The analysis engine is not designed to generate incident reports.

The analysis engine is not designed to update the signatures and rules for attack patterns.

q_ids_anomaly_01_secp8

You are concerned about protecting your network from network-based attacks on the internet. Specifically, you are concerned about attacks that have not yet been identified or that do not have prescribed protections.

Which type of device should you use?

Answers:

- Signature-based IDS
- ***Anomaly-based IDS**
- Antivirus scanner
- Network-based firewall
- Host-based firewall

Explanation:

An anomaly-based intrusion detection system (IDS) can recognize and respond to some unknown attacks. Signature recognition, also referred to as pattern matching or dictionary recognition, looks for patterns in network traffic and compares them to known attack patterns called signatures. Signature-based recognition cannot detect unknown attacks. This system can only detect attacks identified by published signature files.

Antivirus software is a form of signature-based IDS. A network-based firewall filters packets for a network, while a host-based firewall filters packets for a host. Firewalls are typically configured using access control lists that identify specific traffic as allowed or denied.

q_ids_anomaly_02_secp8

Which intrusion detection method involves the analysis engine trained to recognize baseline "normal" traffic and generates an incident when it detects deviations from this baseline?

Answers:

- Signature-based detection
- ***Behavioral- and anomaly-based detection**
- Trend analysis
- Network traffic analysis (NTA)

Explanation:

Behavioral- and anomaly-based detection involves training the engine to recognize any activity that deviates from this baseline (outside a defined tolerance level) to generate an incident. It helps identify zero-day attacks, insider threats, and other malicious activities without a specific signature.

Signature-based detection relies on a database of attack patterns to identify malicious traffic. Effective against known threats, but signature-based detection may miss new or evolving attacks.

Trend analysis aids in understanding an environment over time, helping to identify patterns, anomalies, and potential threats. However, it does not involve the analysis engine.

Network traffic analysis (NTA) is a method of monitoring network availability and activity to identify anomalies, including security and operational issues. However, it does not involve the analysis engine.

q_ids_false_neg_secp8

Which of the following describes the worst possible action by an IDS?

Answers:

- The system detected a valid attack and the appropriate alarms and notifications were generated.
- The system correctly deemed harmless traffic as inoffensive and let it pass.
- The system identified harmless traffic as offensive and generated an alarm.
- ***The system identified harmful traffic as harmless and allowed it to pass without generating any alerts.**

Explanation:

The worst possible action an IDS can perform is identifying harmful traffic as harmless and allowing it to pass without generating any alerts. This condition is known as a false negative.

Positive traffic assessment means that the system detected a valid attack and the appropriate alarms and notifications were generated. Negative traffic assessment means that the system correctly deemed harmless traffic as inoffensive and let it pass. False positive traffic assessment means that the system identified harmless traffic as offensive and triggered an alarm.

q_ids_false_pos_01_secp8

You have configured an NIDS to monitor network traffic.

Which of the following describes harmless traffic that has been identified as a potential attack by the NIDS device?

Answers:

- ***False positive**
- False negative
- Negative
- Positive

Explanation:

A false positive traffic assessment means that the system identified harmless traffic as offensive and generated an alarm or stopped the traffic.

A negative traffic assessment means that the system deemed the traffic harmless and let it pass.

A false negative traffic assessment means that harmful traffic was allowed to pass without any alerts being generated or any actions being taken to prevent or stop it. This is the worst possible action by an IDS.

A positive traffic assessment means that the system detected an attack and the appropriate alarms and notifications were generated or the correct actions were performed to prevent or stop the attack.

q_ids_false_pos_02_secp8

Which of the following describes a false positive when using an IPS device?

Answers:

- ***Legitimate traffic being flagged as malicious.**
- Malicious traffic not being identified.
- Malicious traffic masquerading as legitimate traffic.
- The source address matching the destination address.
- The source address identifying a non-existent host.

Explanation:

On an intrusion prevention system (IPS), a positive match occurs when traffic matches the signature that identifies malicious traffic. A false positive occurs when legitimate traffic is identified as malicious traffic. This situation is undesirable, as it often results in legitimate traffic being rejected. Good IPS signature files result in low false positive rates.

A false negative occurs when malicious traffic is not identified and is, therefore, allowed.

Spoofing is the technique of falsifying the source address in a packet.

q_ids_firewall_rules_secp8

An organization's cybersecurity team has recently set up a new firewall and intrusion detection system (IDS) to strengthen the security of its enterprise infrastructure. The IDS, however, has sent a high number of false positive alerts, which hampers efficient threat monitoring.

The team believes adjusting the firewall rules will decrease these false positives without weakening the network's security.

What strategy should the cybersecurity team implement to fine-tune their firewall rules to reduce the IDS's false positives, ensuring a robust security infrastructure?

Answers:

- Disable firewall rules for less critical services.
- ***Establish firewall rules based on service-specific threat intelligence.**
- Increase the IDS's sensitivity level.
- Allow all traffic through the firewall.

Explanation:

By basing firewall rules on specific threat intelligence, the team can more accurately filter out potential threats while reducing false positives and maintaining security.

Disabling firewall rules for less critical services exposes the network to threats targeting those services, leading to possible security breaches.

Increasing the IDS's sensitivity level could increase false positives rather than decrease them, adding more noise to threat detection.

Allowing all traffic through the firewall would be highly risky as it would expose the network to potential threats, making it easier for malicious entities to gain access to the network.

q_ids_host_01_secp8

As a security precaution, you have implemented IPsec that is used between any two devices on your network. IPsec provides encryption for traffic between devices.

You would like to implement a solution that can scan the contents of the encrypted traffic to prevent any malicious attacks.

Which solution should you implement?

Answers:

- ***Host-based IDS**
- Network-based IDS
- VPN concentrator
- Port scanner
- Protocol analyzer

Explanation:
